Panjab University Research Journal (Science)

The Journal started as “Research Bulletin of East Panjab University” in the year 1950 and continued with this name till 1953. It had 41 Bulletin covering different scientific domain in the period (volume 1-3).

In the year 1954 the journal was named “Research Bulletin of Panjab University” and continued with this name till the year 2002. From the year 1954 till 1958 (volumes 4-9) it published Bulletin 42 to 156. From the year 1959 (volume 10) it started publication in new format and Professor Vishwanath D.Sc. (Cantab), F.N.I. *(Editor-in-Chief)* played a pivotal role in the development of the journal. It is being published regularly as annual volume.

Editor-in-chief

PARALLELISM BETWEEN VARIATIONS OF TAXONOMIC VALUE AND CYTOLOGICAL RESEMBLANCES IN ALLIED SPECIES: SPERMATOGENESIS OF SCORPIONS

By Vishwa Nath *and* Gurdev Kaur Gill

(Department of Zoology, East Panjab University, Government College, Hoshiarpur)

Introduction

Specimens of the scorpion, *Buthus acute-carinatus*, are easily obtainable in Hoshiarpur throughout the year, but more easily in the months of June to September. In view of its availability and the importance of this animal in general, we hoped that investigation of the spermatogenesis of this classical animal might be profitable and might yield important results. This hope has been fully realized.

Gurdev Kaur started this work in April, 1948, with the object of submitting a thesis for the M.Sc. degree of the East Panjab University under the supervision of the senior author.

It was soon discovered that the mitochondria in the spermatogenesis of this species behave exactly as they do in the classical species of the Arizona scorpion, *Centrurus*, worked out by Wilson (1916) inasmuch as in both species the mitochondria of the primary spermatocyte form a ring which, in both meiotic divisions, divides equally, each spermatid receiving two mitochondrial masses of more or less equal size. It may be noted that in all other genera of scorpions whose spermatogenesis has been worked out (*Opisthacanthus*, *Vejovis*, *Hadrurus*, and *Palamnaeus*) the mitochondrial balls do not fuse to form a ring, but remain separate and are more or less equally sorted out to the four spermatids resulting from one primary spermatocyte.

It may be stated that both *Centrurus* and *Buthus*, whose mitochondria behave alike, belong to the family *Buthidae*.

Another important conclusion that we have arrived at is that the acrosome is formed directly from the Golgi body and is not a secretory product thereof.

Regarding technique live scorpions were dissected in normal saline and the testis was fixed in Flemming-without-acetic from 24 to 72 hours. The material fixed in F.W.A. for 48 hours gave very good results. Champy's fluid was also used, but it gave identical results. Bouin's fixative was used for control. Staining was done in 0·5% iron haematoxylin. The material was studied in smears also.

Previous Literature

Wilson's classical work on the spermatogenesis of scorpions (*Opisthacanthus*, *Vejovis*, *Hadrurus*, and *Centrurus*) was published in 1916. Later,

Gatenby and Bhattacharya (1925) published a paper on the spermatogenesis of *Palamnaeus bengalensis* and in the same year Nath published a paper on *Palamnaeus Madraspatensis*.

In all the scorpions the mitochondria are found to be very small and numerous in the spermatogonia. But in the spermatocytes they coalesce into a number of mitochondrial balls which remain separate in all genera except *Centrurus*. These balls do not divide, but are merely sorted out more or less equally in both the meiotic divisions. In *Palamnaeus bengalensis*, according to Gatenby and Bhattacharya, the number of mitochondria in the spermatid varies from four to eleven. The number of mitochondria in the spermatids of *Palamnaeus Madraspatensis* also varies (Nath, 1925). The same is true of *Opisthacanthus*, *Vejovis*, and *Hadrurus*, except that in the first-named the number of mitochondria in the spermatids is six in about 75% out of the two hundred cases counted, whereas in the remaining 25% the number varied from 5 to 7.

But in *Centrurus* (Wilson, 1916) all the mitochondrial balls of the primary spermatocyte coalesce to form a single ring-shaped body, which places itself tangentially to the spindle of the first meiotic division. It is then cut across transversely into two half-rings. At the close of the first meiotic division each half-ring is cut into two parallel rods. In the second meiotic division these rods are cut across transversely into two shorter rods. The spermatocyte ring is thus divided into eight short rods of equal size, each spermatid receiving two such rods. These rods quickly turn into ball-shaped masses. Later, they become attenuated along the axial filament and twist round each other to form a close double spiral, which ultimately becomes so fine as to become invisible as such.

Observations

Primary Spermatogonia

The primary spermatogonia are fairly large cells. As usual, each has a vesicular nucleus. There are one or two deeply staining nucleoli (Text-fig. I, 1). The mitochondria in the primary spermatogonia are granular, and they occupy the usual juxta-nuclear position. They stain a deep blue colour.

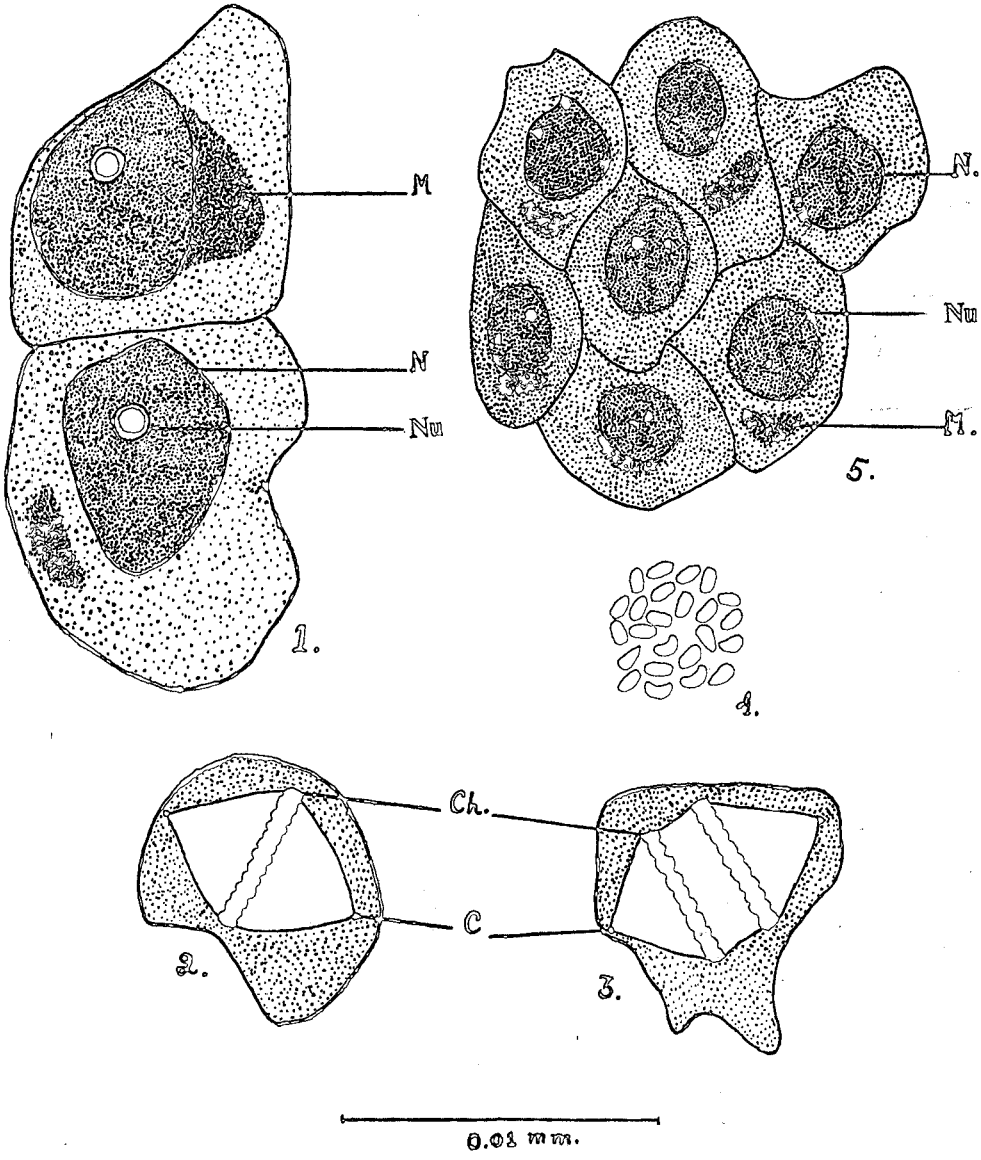
In spite of the most diligent search it has not been possible to observe either the Golgi body or the centrosome, although both these cell elements become conspicuous in subsequent stages of spermatogenesis.

The primary spermatogonia divide to give rise to the secondary spermatogonia (Text-fig. I, 2 and 3). A centrosome is conspicuous at either pole of the spindle. It is worthy of note that the spindle appears as a hyaline fusiform area showing no fibres whatsoever. This picture is similar to the picture of the spindle in the living cells. It is clear therefore that osmic acid causes the least amount of coagulation and that the fibres in the spindle area are artifacts.

The diploid number of chromosomes, as determined by the study of spermatogonial metaphase is 24 in *Buthus acute-carinatus* (Text-fig. I, 4).

Secondary Spermatogonia

The secondary spermatogonia are exactly similar in structure to the primary spermatogonia, except that they are smaller in size (Text-fig. I, 5).



TEXT-FIG. I. 1. Primary Spermatogonia; 2 and 3. Spermatogonial metaphase; 4. Spermatogonial metaphase, polar view (24 chromosomes); 5. Secondary spermatogonia.

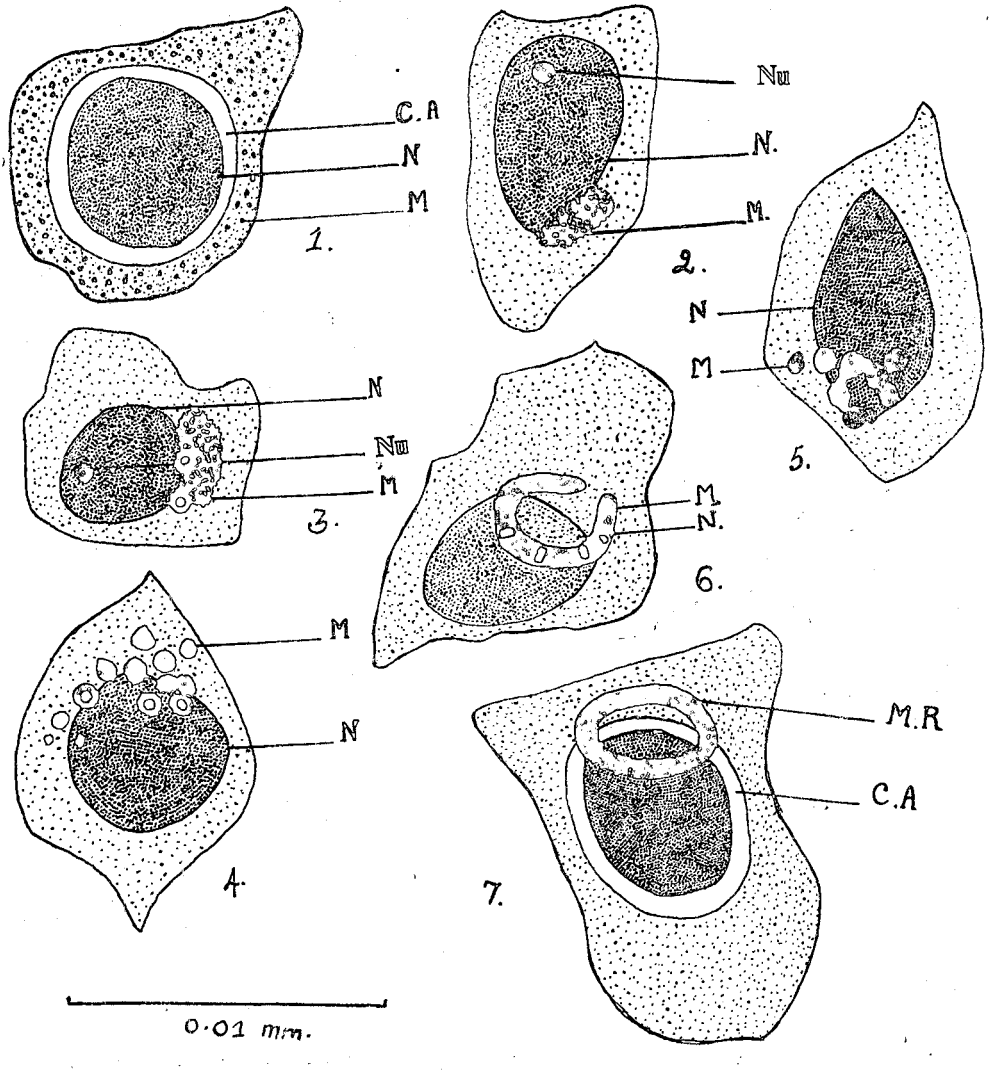
1, 2, 3, and 5 from material fixed in F.W.A. and stained with 0·5% iron haematoxylin, and 4 from material fixed in Bouin's fluid and stained as above.

C., centrosome; *Ch.*, chromosomes; *M.*, mitochondria; *N.*, nucleus; *Nu.*, nucleolus; *T.*, tail.

Spermatocytes

There is no appreciable difference between the primary spermatocytes and the primary spermatogonia, except that the mitochondria in the former do not occupy juxta-nuclear position, but, having grown in size, are distributed evenly throughout the cytoplasm (Text-fig. II, 1).

A remarkable process now takes place which has its parallel only in *Centrurus* as described by Wilson (1916). The mitochondrial granules of the primary spermatocytes, which were hitherto distributed evenly, now take up a juxta-nuclear position and form a dense deeply-staining mass.



TEXT-FIG. II. 1. Primary spermatocyte with scattered mitochondria; 2. Mitochondria closely aggregated at one side of the nucleus; 3 and 4. Mitochondria assuming a vesicular form; 5 and 6. Mitochondria arranging themselves into a ring; 7. Mitochondrial ring.

All from material fixed in F.W.A.

C.A., clear area; *M.R.*, mitochondrial ring.

Gradually, by a progressive process of coalescence, the mitochondrial granules form what may be appropriately described as mitochondrial balls or vesicles. With suitable staining it is possible to demonstrate that each

TEXT-FIG. IV. Stages leading to the formation of the secondary spermatocyte. 1. Late anaphase I showing a break on one side of the mitochondrial ring and an indication of a break on the other side; 2. Telophase I, mitochondrial ring dividing into two half-rings and an extra piece; 3 and 4. Division of the two half-rings into two rods each and an extra ball-like mass; 5. Metaphase I, polar view showing twelve chromosomes; 6 and 7. Secondary spermatocytes with two rod-like pieces and an extra piece of mitochondrial material.

1 from material fixed in F.W.A.; 2–4, 6 and 7 from material fixed in Champy's fixative; 5 from material fixed in Bouin's fluid.

M_1, extra mitochondrial piece.

mitochondrial vesicle shows a chromophilic cortex and a chromophobic medulla (Text-fig. II, 2–5).

The next step in the process consists of a gradual and a progressive fusion of the mitochondrial vesicles to form a complete ring, in which the chromophobic material can be still seen in the form of vacuoles, at least in some cases (Text-fig. II, 6-7 and Text-fig. III, 1 and 2).

During metaphase I the mitochondrial ring places itself tangentially to the mitotic spindle (Text-fig. III, 3–5) and continues to occupy this position even during the early telophase I (Text-fig. III, 6 and 7).

During the late telophase stages of the first meiotic divisions the mitochondrial ring is cut into two half-rings, each secondary spermatocyte receiving one half-ring (Text-fig. IV, 1–4), which quickly breaks up into two parallel rods.

There is, however, one important point of difference between *Buthus acute-carinatus* and *Centrurus*, viz., that in the former species a somewhat round mitochondrial piece is differentiated at an early stage in the equatorial region, and this gets pinched off from each of the two half-rings, and it passes to one of the two secondary spermatocytes (see M_1 in Text-fig. IV, 1–4 and also in Text-fig. IV, 6 and 7). This mitochondrial piece, however, soon fuses with one of the two parallel rods in the secondary spermatocyte (Text-fig. V, 1–3).

During metaphase II the two mitochondrial rods in secondary spermatocyte again place themselves tangentially to the mitotic spindle (Text-fig. V, 4 and 5). In the telophases each mitochondrial rod is cut across in the middle, so that each of the two resulting spermatids will receive two short rods.

In Text-fig. IV, 5 is shown a polar view of the early telophase I, showing the haploid number of chromosomes which is twelve. In Text-fig. V, 9 is shown likewise a polar view of the early telophase II, also showing the reduced haploid number of chromosomes.

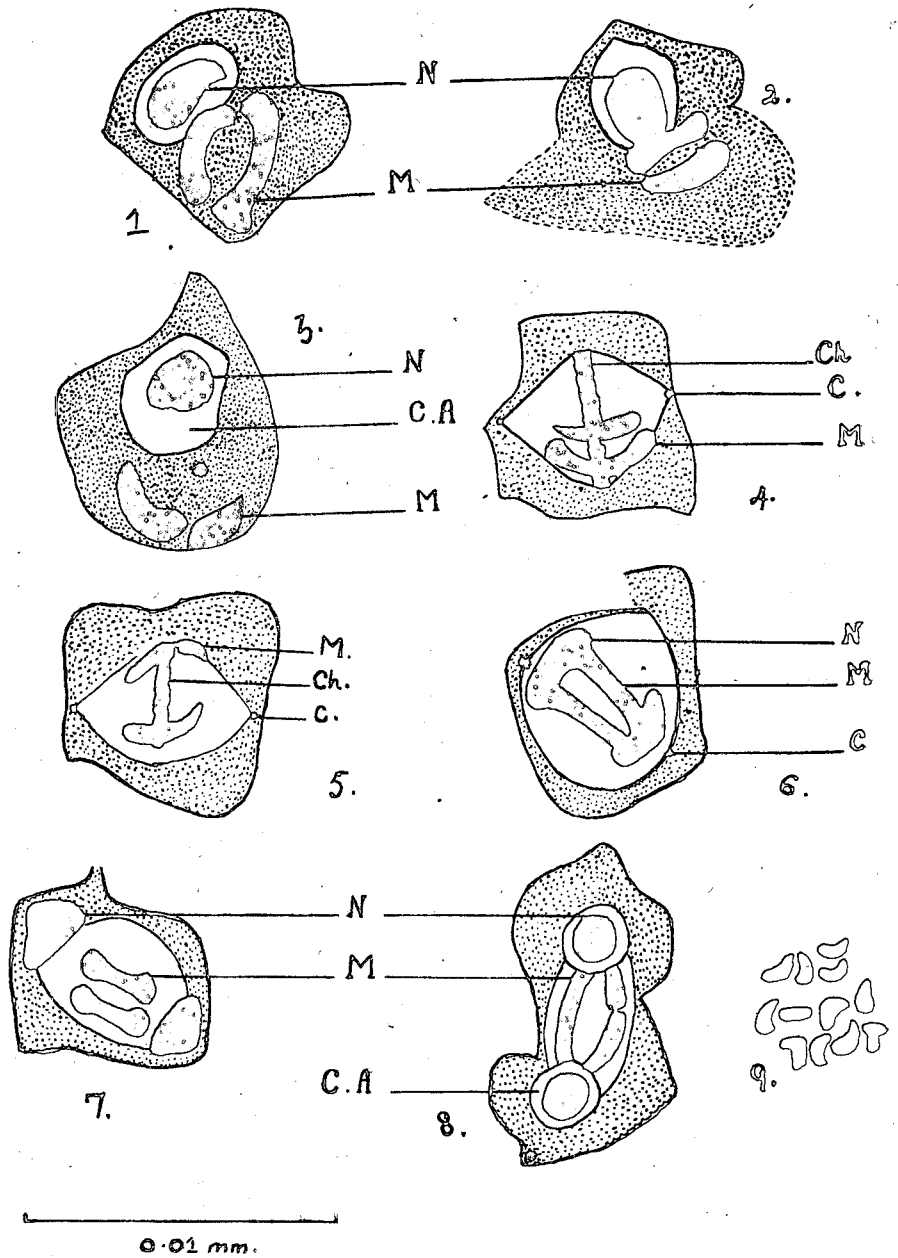
As a rule, it is easy to demonstrate the Golgi body during spermateleosis, but in this species it has been possible to demonstrate it sometimes during earlier stages also (Text-fig. III, 1 and 2). In these two figures the Golgi body clearly consists of two pieces.

Spermateleosis

In the earlier spermatids the two short mitochondrial rods quickly round themselves off and the Golgi apparatus, which hitherto consisted of two pieces, becomes a single compact body by the fusion of these pieces (Text-fig. VI, 1–5). The spermatid nucleus now begins to elongate, and the Golgi body places itself at its anterior end and the two mitochondrial pieces at the posterior end (Text-fig. VI, 6–9).

Soon an axial filament springs up from the base of the nucleus (Text-fig. VI, 10). It soon emerges out of the cell at the posterior end. Due to mechanical disturbance it may not be possible to demonstrate the origin of the axial filament from its natural position, that is, the base of the nucleus (Text-fig. VII, 1–5).

With the elongation of the nucleus of the spermatid the Golgi body begins to grow directly into the acrosome (Text-fig. VII, 6 and 7). At the same time the two mitochondrial masses in each spermatid begin to elongate and assume the form of two thick threads closely twisted round each other



TEXT-FIG. V. Secondary spermatocytes and their divisions. 1–3. Two rod-shaped mitochondria; 4–8. Gradual stages in the division of these two rod-like mitochondria into two equal halves; 9. Metaphase II, polar view.

1–3 from material fixed in Champy's fixative; 4–8 from material fixed in F.W.A.; 9 from material fixed in Bouin's fluid.

(Text-fig. VIII, 1–5). Ultimately the mitochondrial spirals get so attenuated that no trace is left of them in the tail of the ripe sperm, although the sheath of the axial filament is formed definitely from the mitochondrial spirals.

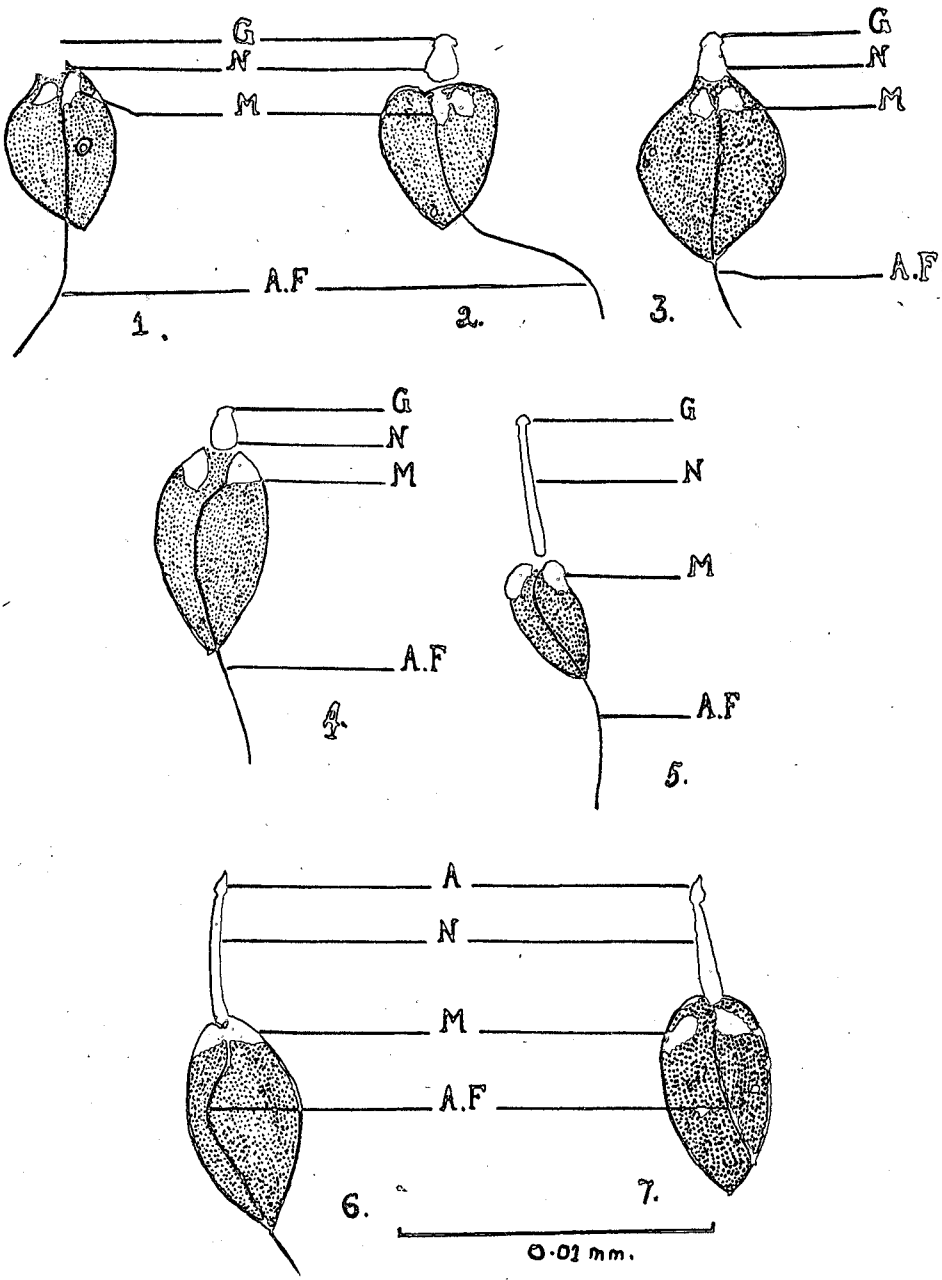
Discussion

We wish to emphasize only three points in this section: firstly, it has to be noted that the distribution of the mitochondrial material to the four spermatids resulting from one primary spermatocyte is equal only in the quantitative sense and not in the qualitative sense. The division of the mitochondrial material is not on a par with the division of a chromosome, which divides equally not only in the quantitative sense, but also in the

qualitative sense. It has therefore been rightly held that chromatin is the *physical basis of heredity par excellence.*

Secondly, it is to be noted that the acrosome is formed directly from the Golgi apparatus and is not a secretory product thereof (*vide* Nath, 1944).



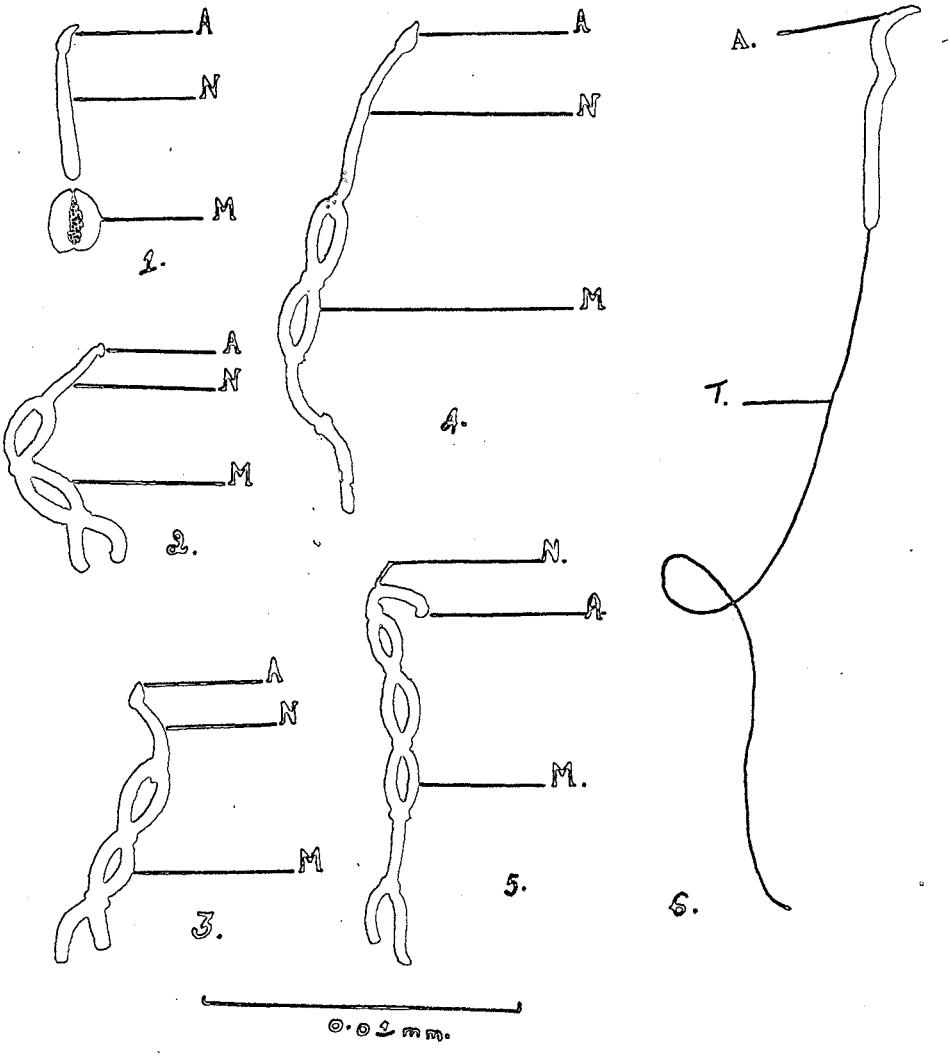
TEXT-FIG. VII. Spermatids showing the formation of the acrosome, elongation of the nucleus, and the origin of the axial filament.

All figs. from material fixed in F.W.A.

A., acrosome.

Lastly, we claim to have produced cytological evidence in support of the taxonomic value of the seemingly unimportant external variations which the taxonomist uses in his work of species building. As has been pointed out earlier by us, *Centrurus* and *Buthus acute-carinatus* have been placed in the scheme of classification close to each other in the family *Buthidae* on the strength of external resemblances which are parallel, as we have proved, to the identical behaviour of the mitochondrial material in these two closely allied species.

A similar parallelism was brought out by Nath in the Decapod sperm (Nath, 1942). In the *Macrura*, as illustrated by *Penaeus indicus*, *Palaemon lamarrei*, and *Panulirus polyphagus*, there is a single large centrosome.



TEXT-FIG. VIII. 1–5. Elongation and twisting of the two mitochondrial pieces to form the tail-sheath of the sperm tail; 6. Ripe sperm with acrosome, head, and the tail.

1–5 from material fixed in F.W.A. and 6 from a smear prepared in F.W.A.

From some Macrura-like ancestors (probably forms somewhat like present-day Penaeidea), with only single centrosome in their sperms, were evolved such Brachyuran forms as have two centrosomes in their sperms (*Paratelphusa* and its allies), and from some of these bicentrosomal forms were, in turn, evolved *Leptodius* and its allies, which have three centrosomes in their sperms. The Anomura seem to have arisen from the Penaeidea-like ancestors by the enormous enlargement of the centrosomal apparatus and its differentiation into three well-defined parts. It was shown by Nath that this process of evolution based on cytological difference runs parallel to the process evolved by the taxonomists inasmuch as the taxonomists are generally agreed that the *Penaeidea* are the most primitive of the *Decapoda*.

Summary

1. The remarkably equal distribution of the mitochondrial material in the spermatogenesis of *Buthus acute-carinatus* has been fully described.

2. The acrosome is formed directly from the Golgi body and is not a secretory product thereof.

3. Cytological evidence in support of the taxonomic value of seemingly unimportant external variations has been produced.

TABLES OF DISTRIBUTIONS[1]

By HANSRAJ GUPTA, *Government College, Hoshiarpur*

1. Let $u(m, a)$ denote the number of distributions of m unlike things into a ($< m$) groups; i.e. the number of ways in which m men can be accommodated in exactly a similar apartments, no apartment being left vacant. Thus $u(4, 3) = 6$, because four men A, B, C and D can be placed in three apartments in the following six ways:—

(1) (A), (B), (C, D); (2) (A), (D), (B, C); (3) (A), (C), (B, D);
(4) (B), (D), (A, C); (5) (B), (C), (A, D); (6) (C), (D), (A, B).

Now suppose, we have to place $(m+1)$ men in a apartments. Corresponding to each of the $u(m, a)$ distributions of the first m men into a apartments there are a ways of accommodating the $(m+1)$th person, because he can be placed in any one of the a apartments. Again, corresponding to each one of the $u(m, a-1)$ distributions of the first m persons into $(a-1)$ apartments, there is one way of accommodating the $(m+1)$th person and that is in the a-th apartment. Hence, we have the fundamental relation:—

$$u(m+1, a) = a.\, u(m, a)+u(m, a-1), \quad .. \quad .. \quad (1)$$

which holds when $m \geqslant a > 1$. Moreover,

$$u(m, 1) = 1 = u(m, m), \quad m > 1; \quad .. \quad .. \quad .. \quad (2)$$

and we take

$$u(0, 0) = 1, \quad .. \quad .. \quad .. \quad .. \quad (3)$$

$$u(m, a) = 0, \text{ when } 0 < m < a, \text{ or } a < 0. \quad .. \quad .. \quad (4)$$

The tables that follow, give the values of $u(n, a)$ for $1 \leqslant a \leqslant n \leqslant 50$; and have been computed mainly with the help of relation (1). We give also the values of

$$U(n) = \sum_{m=1}^{n} u(m, a), \quad .. \quad .. \quad .. \quad (5)$$

for values of n up to 50. These are the unrestricted distributions of n dissimilar things into groups. Thus $U(6) = 203$.

2. Let[2] $S(a) = \sum_{m=a}^{\infty} u(m, a)\,.\,x^{-m}$,

then $$\frac{a}{x}\,.\,S(a) = \sum_{m=a+1}^{\infty} a\,.\,u(m-1, a)\,.\,x^{-m}.$$

Subtracting, we get

$$\frac{x-a}{x}\,S(a) = \sum_{m=a}^{\infty} u(m-1, a-1)\,.\,x^{-m} = \frac{S(a-1)}{x}.$$

Hence $$S(a) = \frac{1}{x-a} . S(a-1) = \frac{1}{(x-a)} \cdot \frac{1}{(x-a+1)} . S(a-2) = \ldots .$$

$$= \{(x-1)(x-2)(x-3) \ldots (x-a)\}^{-1};$$

because $$S(1) = \frac{1}{x} + \frac{1}{x^2} + \frac{1}{x^3} + \ldots = \frac{1}{x-1} .$$

Thus $u(m, a)$ is the coefficient of x^{-m} in the expansion of

$$\{(x-1)(x-2)(x-3) \ldots (x-a)\}^{-1}. \quad .. \quad .. \quad (6)$$

Breaking (6) into partial fractions, we find that

$$(a-1)!\, u(m, a) = a^{m-1} - \binom{a-1}{1}(a-1)^{m-1} + \binom{a-1}{2}(a-2)^{m-1} - \ldots .$$

$$\ldots . + (-1)^{a-1}\binom{a-1}{a-1} . 1^{m-1} . \ldots \quad (7)$$

In particular,

$$u(m, 1) = 1,$$

$$1!\, u(m, 2) = 2^{m-1} - 1,$$

$$2!\, u(m, 3) = 3^{m-1} - 2 . 2^{m-1} + 1.$$

Again[3] $(e^x - 1)^a = e^{ax} - \binom{a}{1} e^{(a-1)x} + \binom{a}{2} e^{(a-2)x} - \ldots . + (-1)^a \binom{a}{a}$.

Coefficient of x^m in the expansion of $(e^x - 1)^a$

$$= \frac{a^m}{m!} - \binom{a}{1}\frac{(a-1)^m}{m!} + \binom{a}{2}\frac{(a-2)^m}{m!} - \ldots + (-1)^{a-1}\binom{a}{a-1}\frac{1^m}{m!}, \; m \geqslant 1;$$

$$= \frac{a!}{m!}\, u(m, a).$$

Hence $U(m)$ is the coefficient of $\frac{x^m}{m!}$ in

$$\sum_{a=1}^{m} \frac{(e^x-1)^a}{a!}, \text{ i.e. in } \sum_{a=0}^{\infty} \frac{(e^x-1)^a}{a!} \text{ or } \frac{e^{e^x}}{e} .$$

In other words,

$$e^{e^x - 1} = 1 + \frac{U(1)}{1!}x + \frac{U(2)}{2!}x^2 + \frac{U(3)}{3!}x^3 + \ldots . + \frac{U(m)}{m!}x^m + \ldots . \quad .. \quad (8)$$

Differentiating, we get

$$e^x . e^{e^x - 1} = \sum_{m=0}^{\infty} \frac{U(m+1)}{m!} x^m .$$

Also $$e^x . e^{e^x - 1} = \sum_{t=0}^{\infty} \frac{x^t}{t!} \cdot \sum_{s=0}^{\infty} \frac{U(s)}{s!} x^s .$$

Equating the coefficients of x^m in these two expressions, we have

$$U(m+1) = U(0) + \binom{m}{1}U(1) + \binom{m}{2}U(2) + \ldots . + \binom{m}{m}U(m). \quad .. \quad (9)$$

where $U(0) = 1$.

The value of $U(50)$ has been checked [4] with the help of (9).

3. The following congruences were very useful to me in checking the results as the work of computation proceeded.

Throughout this section p denotes a prime > 2.

As a direct consequence of Fermat's Theorem, we have

$$u(p, a) \equiv 0 \pmod{p}, 1<a<p; \quad \ldots \quad \ldots \quad \ldots \quad (10)$$

and
$$\equiv 1 \pmod{p}, a = 1 \text{ or } p. \quad \ldots \quad \ldots \quad (11)$$

Moreover

$$u(p+m, a) = u(m+1, a)+u(m, a-p) \pmod{p}. \quad \ldots \quad (12)$$

For supposing (12) to be true for every positive $m \leqslant n-1$, we have

$$\begin{aligned} u(p+n, a) &= a \,.\, u(p+n-1, a)+u(p+n-1, a-1), \\ &= a\{u(n, a)+u(n-1, a-p)\} \\ &\qquad +\{u(n, a-1)+u(n-1, a-p-1)\} \pmod{p}, \\ &\equiv \{a \,.\, u(n, a)+u(n, a-1)\} \\ &\qquad +\{a \,.\, u(n-1, a-p)+u(n-1, a-p-1)\} \pmod{p}, \\ &\equiv u(n+1, a)+u(n, a-p) \pmod{p}. \end{aligned}$$

The result follows readily by induction.

From (12) we obtain without difficulty

$$U(p+m) \equiv U(m+1)+U(m) \pmod{p}; \quad \ldots \quad \ldots \quad (13)$$

where $U(0) = 1$ as already stated.

Using (13), k times in succession, we get

$$\begin{aligned} U(kp+m) \equiv U(m+k)+\binom{k}{1} U(m+k-1)+\binom{k}{2} U(m+k-2)+\ldots. \\ \ldots+\binom{k}{k} U(m) \pmod{p}. \quad \ldots \quad (14) \end{aligned}$$

As a particular case of (14), we have

$$\begin{aligned} U(kp) &\equiv U(k)+\binom{k}{1} U(k-1)+\binom{k}{2} U(k-2)+\ldots.+\binom{k}{k} U(0) \pmod{p}, \\ &\equiv U(k+1) \pmod{p}. \quad \ldots \quad \ldots \quad \ldots \quad \ldots \quad \ldots \quad \ldots \quad (15) \end{aligned}$$

4. *An Inequality.* For every $m > 0$,

$$U(m) \leqslant \frac{(m+2)!}{3 \,.\, 2^m}. \quad \ldots \quad \ldots \quad \ldots \quad (16)$$

Supposing this to hold for every $m \leqslant n-1$, we have

$$\begin{aligned} U(n) &= U(n-1)+\binom{n-1}{1} U(n-2)+\binom{n-1}{2} U(n-3)+\ldots. \\ &\qquad +\binom{n-1}{n-1} U(0), \\ &\leqslant \frac{(n+1)!}{3 \,.\, 2^{n-1}}+(n-1).\frac{n!}{3 \,.\, 2^{n-2}}+\frac{(n-1)(n-2)}{2!}.\frac{(n-1)!}{3 \,.\, 2^{n-3}}+\ldots. \\ &\qquad +(n-1).\frac{3!}{3 \,.\, 2}+1, \end{aligned}$$

$$< \frac{(n+1)!}{3 \cdot 2^{n-1}} \left\{ 1 + \frac{2}{1!} + \frac{2^2}{2!} + \frac{2^3}{3!} + \ldots \right\},$$

$$< \frac{(n+1)!}{3 \cdot 2^{n-1}} \cdot e^2,$$

$$< \frac{(n+2)!}{3 \cdot 2^n}, \text{ provided } \frac{n+2}{2} > e^2.$$

The result being true for every $m < 2(e^2-1)$, is true for every $m > 0$.

5. 1. *Some Asymptotic Results.*

Let $(m-1)/a = y$, where y is not necessarily an integer.

Then for large values of m and a,

$$U(m, a) = \frac{1}{(a-1)!} \left\{ a^{m-1} - \binom{a-1}{1}(a-1)^{m-1} + \binom{a-1}{2}(a-2)^{m-1} - \ldots \right\},$$

$$= \frac{a^{m-1}}{(a-1)!} \left\{ 1 - \binom{a-1}{1}\left(1-\frac{1}{a}\right)^{ay} + \binom{a-1}{2}\left(1-\frac{2}{a}\right)^{ay} - \ldots \right\},$$

$$\sim \frac{a^{m-1}}{(a-1)!}(1-e^{-y})^{a-1}.$$

Similarly, $u(m, a-1) \sim \frac{a^{m-1}}{(a-2)!} e^{-y}(1-e^{-y})^{a-2}$,

and $u(m, a+1) \sim \frac{a^{m-1}}{a!} e^{y}(1-e^{-y})^{a}$.

Hence $u(m, a-1) \leqslant u(m, a) \geqslant u(m, a+1)$ for large m, if

$a \leqslant e^y \leqslant a+1$, i.e. $\log a \leqslant y \leqslant \log (a+1)$.

Thus $u(m, a)$ is maximal for a given large m, if

$$\log a < \frac{m-1}{a} < \log (a+1). \quad \ldots \quad \ldots \quad \ldots \quad (17)$$

For $m = 50$, this gives $a = 17$, while $a = 16$ from the table.

5. 2. Let r denote the value of a for which $u(m, a)$ is maximal.

Then $U(m) = \sum_{a=1}^{r} u(m, a) + \sum_{a=r+1}^{\infty} u(m, a)$,

$$\sim r^{m-1}\left\{ \frac{(1-e^{-y})^{r-1}}{(r-1)!} + \frac{e^{-y}(1-e^{-y})^{r-2}}{(r-2)!} + \ldots \right\}$$

$$+ r^{m-1}\left\{ \frac{e^{y}(1-e^{-y})^{r}}{r!} + \frac{e^{2y}(1-e^{-y})^{r+1}}{(r+1)!} + \ldots \right\}, y = \frac{m-1}{r};$$

$$\sim \frac{r^{m-1}}{e^{y(r-1)}} \sum_{t=0}^{m} \frac{(e^y-1)^t}{t!},$$

$$\sim \frac{r^{m-1}}{e^{y(r-1)}} \exp (e^y-1).$$

Since $y = \log r$ nearly,

$$U(m) \sim r^{m-r}\, e^{r-1}. \qquad \ldots \quad \ldots \quad \ldots \quad (18)$$

For $m = 50$, taking $r = 16$, this gives

$$\log_{10} U(50) = 34 \log_{10} 16 + 15 \log_{10} e,$$
$$= 34 \times 1{\cdot}20412 + 15 \times 0{\cdot}43429,$$
$$= 47{\cdot}45443;$$

while

$$\log_{10} U(50) = 47{\cdot}26879.$$

Even if we were to take $r = 17$, as given by (17), we would get

$$\log_{10} U(50) = 47{\cdot}55349.$$

Within the limits of the table, the value of $\log_{10} U(m)$ computed from (18) exceeds the true value by $< 0{\cdot}3$.

For forming a rough estimate of the value of $U(m)$ for large m, (18) is thus very useful indeed.

A TABLE OF VALUES OF LIOUVILLE'S FUNCTION $L(t)$

By HANSRAJ GUPTA, *Government College, Hoshiarpur.*

1. If p denotes a prime ≥ 2, then for positive integral values of t, Liouville's Functions $\lambda(t)$ and $L(t)$ are defined by the relations

$$\lambda(0) = 0, \quad \lambda(1) = 1, \quad \lambda(pt) = -\lambda(t)$$

and
$$L(t) = \lambda(1)+\lambda(2)+\lambda(3)+\ldots+\lambda(t).$$

Thus
$$\lambda(475) = -\lambda(95) = \lambda(19) = -\lambda(1) = -1.$$

In 1919, Polya[1] conjectured that for values of $t \geq 2$,

$$L(t) \leq 0.$$

He verified this conjecture for values of t up to 1500.

In 1940, at the suggestion of Dr. Chowla, I computed a table giving the values of $\lambda(t)$ and $L(t)$ for values of t up to 20000, and found Polya's conjecture to be true to that extent. The following is a specimen of this table:

t		$\lambda(t)$	$-L(t)$
15801	3.5267	−1	145
15802	2.7901	1	144
15803	p	−1	145
15804	2.7902	−1	146
15805	5.3161	−1	147
15806	2.7903	−1	148
15807	3.5269	−1	149
15808	2.7904	1	148
15809	p	−1	149
15810	2.7905	−1	150

The above table is here presented in a condensed form. It gives the value of $-L(t)$ when t is a multiple of 5 and of $\lambda(t)$ when t is not a multiple of 5. The value of $-L(t)$ when t is not a multiple of 5 and of $\lambda(t)$ when t is a multiple of 5 are readily found with the help of the two fundamental relations:

(1) $$L(t) = L(t-1)+\lambda(t), \quad \text{and}$$

(2) $$\lambda(5t) = -\lambda(t);$$

or by making use of the subsidiary tables of section 3.

2. To find the value of $-L(5t)$, we write

$$t = 5m+n, \text{ where } 0 \leq n \leq 4.$$

The value of $-L(5t)$ is then found directly from the table.

Thus, when $t = 1183$, we have $m = 236$ and $n = 3$.
Hence, looking up the entry in front of 236 (in column one) and under 3 (in the top row), we obtain

$$-L(5915) = 53.$$

To find the value of $\lambda(5t+k)$, $k = 1, 2, 3, 4$;
we again write t in the form $5m+n$. Looking up the entry in the same row as m and in the same column as Δ_n, we get a number r between 0 and 15. We write r as a four-figure number in the scale of 2. Thus, if $r = 3$, we write it as 0011. Changing each zero into -1 in this representation of r, we get in order the values of

$$\lambda(5t+1), \lambda(5t+2), \lambda(5t+3) \text{ and } \lambda(5t+4).$$

Thus, to find the value of $\lambda(5918)$ say, we look up the entry in front of 236 and in the column Δ_3. This is found to be 5. Now, 5 is 0101 in the scale of 2. This gives the scheme:

$$-1, 1, -1, 1.$$

Hence, $\lambda(5916) = -1, \lambda(5917) = 1, \lambda(5918) = -1, \lambda(5919) = 1.$

The value of $-L(5918)$ is now readily found.

In fact, $-L(5918) = -L(5915) - \lambda(5916) - \lambda(5917) - \lambda(5918)$,

$$= 53 + 1 - 1 + 1 = 54.$$

Lastly, to find $\lambda(t)$ when t is a multiple of 5, we write

$$t = 5^{\alpha} . t_1, \text{ where } (t_1, 5) = 1.$$

Then

$$\lambda(t) = (-1)^{\alpha} . \lambda(t_1),$$

where $\lambda(t_1)$ can be found from the table as stated above.

3. For ready reference, we give below the values of $\lambda(5t+k)$ corresponding to the numbers 0 to 15 in the Δ—columns, as also the additives for the values of $-L(5t+k)$.

	$\lambda(5t+k)$				$-L(5t+k) = -L(5t) + \ldots$			
k	1	2	3	4	1	2	3	4
0	−1	−1	−1	−1	1	2	3	4
1	−1	−1	−1	1	1	2	3	2
2	−1	−1	1	−1	1	2	1	2
3	−1	−1	1	1	1	2	1	0
4	−1	1	−1	−1	1	0	1	2
5	−1	1	−1	1	1	0	1	0
6	−1	1	1	−1	1	0	−1	0
7	−1	1	1	1	1	0	−1	−2
8	1	−1	−1	−1	−1	0	1	2
9	1	−1	−1	1	−1	0	1	0
10	1	−1	1	−1	−1	0	−1	0
11	1	−1	1	1	−1	0	−1	−2
12	1	1	−1	−1	−1	−2	−1	0
13	1	1	−1	1	−1	−2	−1	−2
14	1	1	1	−1	−1	−2	−3	−2
15	1	1	1	1	−1	−2	−3	−4

4. Let $t(h)$ be the least value of t for which

$$-L(t) = h.$$

Then the following table gives the values of $t(h)$ for values of h from 0 to 150.

$h\rightarrow$ $\downarrow$	0	1	2	3	4	5	6	7	8	9
	0	3	8	13	20	31	32	53	76	79
1	80	117	176	181	182	193	200	283	284	285
2	286	293	440	443	468	661	678	683	684	1075
3	1076	1087	1088	1091	1092	1093	1106	1109	1128	1129
4	1130	1131	1132	1637	1638	1753	1756	1759	1760	2699
5	2700	2703	2712	2713	2714	2715	2720	2731	2732	2739
6	2742	2769	2770	2801	2802	2803	2804	4157	4256	4261
7	4364	4373	4526	4527	4528	6317	6318	6381	6390	6391
8	6392	6397	6398	6399	6480	6481	6482	6575	6582	6859
9	6864	6877	6878	6969	6972	6975	6976	6977	6978	6987
10	6988	6997	7026	7027	9686	9689	9690	9695	9696	9697
11	9698	9699	9700	9719	9720	9721	9724	9725	9726	9789
12	9792	9795	9816	9817	9822	9823	9836	9837	9840	15669
13	15670	15671	15672	15675	15676	15679	15680	15745	15750	15753
14	15756	15791	15792	15795	15798	15799	15804	15805	15806	15807
15	15810	>20000								

Within the limits of the table, $\{L(t)\}^2/t$ is the greatest when $t = 9840$, its value being just less than 5/3 then. It thus appears that

$$\left|L(t)\right| = O(t^{\frac{1}{2}}).$$

5. The following table will show the main variations in the value of $L(t)$ as t increases from 2 to 20000.

t	$-L(t)$	t	$-L(t)$
2	0	3281	7
468	24	4528	74
586	0	5645	9
684	28	7027	103
880	6	8512	14
1132	42	9840	128
1411	3	12798	32
1760	48	15810	150
2264	8	19680	10
2804	66

AIR-CONTROL THERMO-REGULATOR.

By M. L. Lakhanpal.

Temperature changes affect the value of most of the physical and chemical constants so that the measurements of this kind have to be necessarily carried out at fixed temperature in a thermostat. Thermostat has therefore become the need of almost every research bench. Various devices of thermo-regulators have so far been made on the following general types.

1. Gas Regulators .. (1)
2. Electric Relay type .. (2)
3. Thyratron Relay type .. (1)

'Air-control thermo-regulator' is a modification of the second type and is so named for the control at different temperatures is done by decreasing or increasing the quantity of air enclosed in the thermo-regulator by means of a glass stopper.

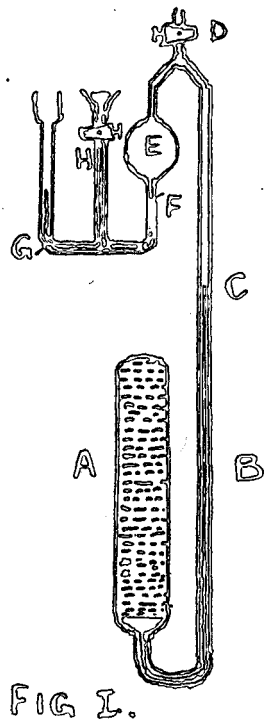

FIG. I.

Construction.

It consists of a toluene tube A of $1\frac{1}{4}''$ diameter bore joined to a glass tube of 5–8 mm. diameter B which is filled with mercury coming to level C. The tube is bent into a U-tube as shown in Fig. 1 and a ground glass stopper is sealed to it at the point D. A bulb of about 1 c.c. in volume is blown in the U-tube at E. Platinum points (3) are sealed at the points F and G. Mercury level in the U-tube is adjusted at F by means of a side tube bearing a glass stopper H.

The platinum joints are joined to the mains or 90 volts battery as shown in the circuit Figure II in series with the electric heater. For better

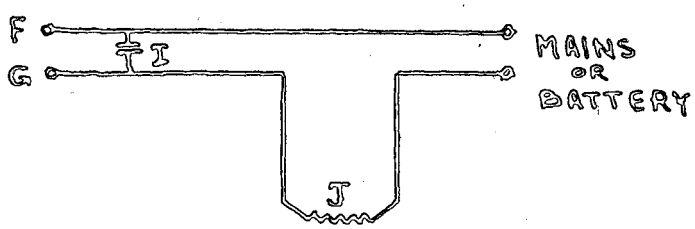

Fig. II.

control of temperature the wattage of the electric heater should depend upon the difference of the required and the atmospheric temperatures,—more the difference, more the wattage. A condenser I of suitable capacity is used as shown to minimize the sparking at F. Two aluminium plates (4) immersed in distilled water may be used as a condenser.

Working of the Apparatus.

For the maintenance of any temperature, open the ground glass stopper at D. Adjust the level of mercury at the platinum point F, by means of ground glass stopper H. Heater circuit being on the required temperature is reached. Close the stopper D. Any further increase in temperature will push down the mercury level at F and thus breaks the heater circuit. Thermostat will cool because of radiation till the circuit is again made. For regulation to exact temperatures adjustment is possible by the stopper H.

This system has the advantage of doing away with relay system which suffers from the possibility of sticking and it consumes much less current. It can also be made available to any laboratory having a glass blower.

Sparking fouls the mercury level if condenser is not used. With the use of a condenser I of suitable capacity and condenser oil over the surface of mercury it is minimized.

It can as well be used with thyratron relay to avoid least amount of fouling of mercury. Thermo-regulators are usually connected in the grid circuit (1) of the tube but in this regulator this connection being impossible, it is connected in the filament circuit as shown in Figure III. In this way with the make and break of filament circuit the current in the heater is switched on and off. Filament voltage and the grid potential will depend upon the characteristic curves of the thyratron tube used.

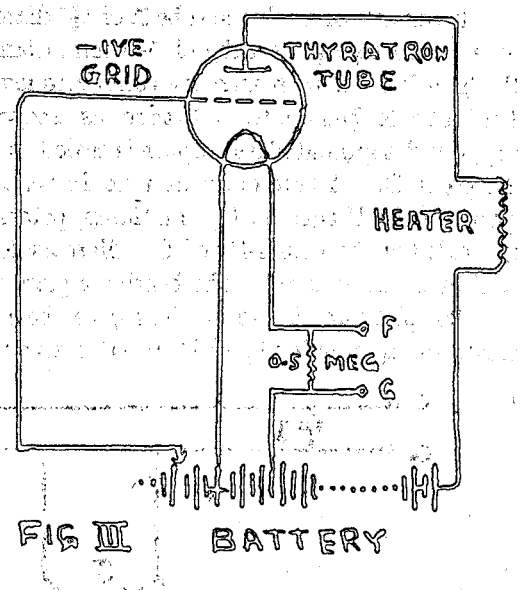

FIG III

It will be clear that filament shall not reach red heat so soon to be able to transfer full current to the heater immediately. Thus the current for the first few seconds will increase with time till it reaches red heat. So an equilibrium will be attained at a certain temperature of filament with the make and break at F, which will transfer just sufficient current to the heater to make up for the radiation of heat.

SPERMATOGENESIS IN THE SPIDER, *PLEXIPPUS PAYKULLI*

By GANPATI PARSHAD SHARMA, *M.Sc., Ph.D. (Panjab), Ph.D. (Edinburgh).*

CONTENTS

INTRODUCTION

Warren (1925) in a letter to *Nature* (September 12) reported that the spermatogenesis of some spiders especially *Palystes natalius* Karsch exhibited interesting peculiarities which did not readily accord with the rigid scheme required by the chromosome hypothesis of heredity. According to him the spermatogonial nuclei divide only by amitosis and the spermatozoa arise in the following two different ways:—

(*a*) The nucleus of the spermatocyte buds or fragments in a somewhat irregular manner and gives rise to a small cluster of nuclei, each of which becomes surrounded by differentiated cytoplasm. These small cells are the spermatids and their number seems to be more than four. The nucleus of the spermatid now becomes hollow and the chromatin concentrates at one pole to give rise finally to the spermatozoon which later on spreads over the cytoplasmic vesicle like a fish embryo stretched over its yolk sac.

(*b*) The numerous chromatin granules of the spermatocyte are condensed to form a considerable number of large masses resembling definitive chromosomes. These chromatin masses become more or less rounded and uniform in size. The cytoplasm of the spermatocyte now disappears and each of these free chromatin bodies becomes hollow to produce one spermatozoon which is differentiated peripherally. These spermatozoa are somewhat smaller than those formed by the first method.

At the suggestion of Prof. J. Bronte Gatenby who adversely criticized Warren's work in a letter to *Nature* (October 3, 1925), Dr. S. D. King worked out the spermatogenesis of the spider, *Amaurobius* sp. and published her results in a letter to *Nature* (October 17, 1925). According to her the whole process of spermatogenesis is quite normal without any evidence of amitosis either in the spermatogonial or spermatocyte divisions. Abnormal spermatids, however, are also formed either by an extra division of the ordinary spermatids or by degeneration of normal forms.

In view of these conflicting accounts the present work was undertaken to work out, if possible, the whole process of spermatogenesis in this ancient group of spiders. This material was considered all the more valuable as none of the previous workers had paid any attention whatsoever to such important cell inclusions as the Golgi elements and the mitochondria. Indeed even the names of these important cell components do not figure in the previous accounts.

It gives me great pleasure to acknowledge my deep indebtedness to Dr. Vishwa Nath, for his helpful suggestions and criticism during the course of this investigation which was carried out in the Department of Zoology, Government College, Lahore. For the identification of the material I am thankful to Mr. Sukh Dyal Malik.

Previous Literature

The earliest paper on spider spermatogenesis is that of Carnoy (1885) who has described in detail the process of cell division in male germ cells of a number of spiders. The whole of his Plate V beautifully illustrates the division stages but still his work has no direct bearing on modern spermatogenetic investigations. This is not surprising as the cytologists in those days did not properly follow the sequence of changes during the maturation divisions.

Wagner's (1896*a*) complete paper, published in the Russian language, is not available anywhere. Nor has it been possible to obtain it from Russia. However, from a preliminary report (1896 *b*) and from several reviews I conclude that Wagner's work is quite comprehensive. He has traced the history of the germ cells from the earliest spermatogonium to the ripe sperm in *Agalena*. Previous workers had described the spider spermatozoon as of a disc-like, aberrant form having no resemblance to the normal type. Wagner was the first worker to point out that the peculiar spider sperm is essentially normal inasmuch as it possesses the head, tail and the apical body. He also demonstrated that the disc-like form results from the rolling up of the ripe sperm.

Montgomery (1905) worked on *Lycosa insopita* and described the heterochromosome or the accessory chromosome as arising from two spermatogonial chromosomes. He, however, could not trace the course of this body through the meiotic divisions but on account of the similarity in its formation he suggested that it may behave like the other chromosomes, dividing first reductionally and then equationally.

Bösenberg (1905) in his remarkable paper on the spermatogenesis of Arachnida has described in detail the process of spermateleosis in *Lycosa*. Starting from the telophase of the second meiotic division he has very carefully followed the development of the spermatid nucleus and the idiozome. The latter, according to him, is formed from the disappearing spindle fibres. He has also described the division of the centrosome into a proximal and a distal portion. The distal centrosome moves towards the cell wall and from it is given out a delicate extra-cellular axial filament. The proximal centrosome moves over or through a portion of the nucleus and later becomes quite large. It is then known as the 'connecting piece' or the 'middle piece'. Both the proximal and the distal centrosomes are connected by an intra-cellular filament. The apical body, which, according to Bösenberg, is derived from the idiozome vesicle, reveals in its middle a delicate filament bearing a small granule at its tip. This is derived from the 'Connecting piece'.

Berry (1906) was the first worker to report dimorphism in spider spermatozoa. She worked on *Epeira* and showed that the odd chromosome or the accessory chromosome passed undivided to one pole during the first meiotic division which was reductional for the ordinary chromosomes. During the second meiotic division the odd chromosome also divided equationally like the other ordinary chromosomes. She derived the odd chromosome from one spermatogonial chromosome.

Wallace (1909) published her complete paper on the spermatogenesis of *Agalena nævia*. In this communication, while she pointed out the discrepancies in the conclusions of the previous workers, she also mentioned two chief errors in her own previous investigations (1900, 1905). The first error was that she failed to notice the division of the accessory chromosomes during the second meiotic division and the second was that she could not find the tail of the spermatozoon. Both these points have been fully discussed in her last paper in which she has also attempted to bring the observations of earlier workers in line with her own results.

Painter (1914) worked on thirteen different species of spiders but confined his studies only to the autosomes, accessory chromosomes and Ctetosomes, etc. He even did not describe the process of spermateleosis and the ripe sperm.

Warren (1925 and later) has also made an extensive study of the spermatogenesis in a large number of spiders and has described many different ways with regard to the formation of the ripe spermatozoon. He has consistently stated that the germinal nuclei divide only by amitosis. Spermatogonia can also divide without mitosis to form spermatocytes. In some spiders, according to him, even the primary spermatocytes may further divide amitotically to form secondary spermatocytes and spermatids. Chromatin structures indistinguishable from spermatozoa are also formed in cells which have originated either without mitosis at all or without the full complement of mitotic divisions characteristic of typical spermatogenesis. In many species there may be formed two kinds of spermatozoa originating in different lobules of the testis. The presence of typical spermatogenesis in many spiders, according to Warren, indicates

that the various atypical methods which have been observed are to be regarded as simplification of the typical process rather than as something fundamentally new or as a survival of the primitive methods. Warren has also described the origin of more than one sperm from a single spermatid. In none of his papers he has been able to identify the centrosome, acrosome and chondriosome, etc.

Material and Methods

The spider, *Plexippus paykulli* (Audouin) is commonly met with in houses in Lahore. I collected a large number of them from the vicinity of the Zoological laboratories of the Government College, Lahore. The male can be easily distinguished from the female by the presence of a pair of black longitudinal bands on the white cephalothorax and abdomen. In the female the cephalothorax and the abdomen are dusty brown in colour and these have a pair of deep brown lateral bands.

For preserving the testes the cephalothorax of the spider is first removed by means of a sharp blade of a safety razor. The abdomen is then cut open from the side under normal saline with a fine pair of scissors. The testes which are in the form of a pair of translucent and slightly convoluted tubes lie embedded on the ventral surface of the brown liver. The latter occupies almost the entire abdominal cavity. These testicular tubes are then carefully separated from the liver using a pair of fine needles. In some cases it becomes quite difficult to distinguish the tubular testes from the whitish spinning glands which lie immediately below them.

The testicular tubes thus taken out were fixed in Flemming-without-acetic and were prepared for sectioning in the usual way. Sections were cut 5-6μ thick and these were stained with 0·5% iron-hæmatoxylin. Smears of the testicular material were also made in Flemming-without-acetic diluted with an equal quantity of water and these were also stained with 0·5% iron-hæmatoxylin. Bouin's followed by 0·5% iron-hæmatoxylin was used as control.

Feulgen's reaction was also tried after fixation in strong Flemming solution.

Observations

The earliest spermatogonia of *Plexippus paykulli* (Audouin) are large, more or less, rounded or oval cells with comparatively large nuclei (Plate I, fig. 1). The nucleus which reveals inside it a number of faintly staining chromatin granules arranged on a spireme-like net work, is surrounded by a thin layer of cytoplasm showing no granulation whatsoever. In the late spermatogonia, however, the cytoplasm on one side of the nucleus appears to be denser and very often it is now possible to make out a few greyish granules in this area. These granules are most probably the mitochondria (Plate I, fig. 2).

During the spermatogonial metaphase (Plate I, fig. 3) the rod-like chromosomes are so closely packed together that it is impossible to make an approximately accurate count of them. In Plate I, fig. 4, the chromosomes arrange themselves in such a way that they occupy almost the

whole of the spindle area and consequently it is not possible to observe any spindle fibre. At each pole of the spindle area there is a sharply staining granule, the centrosome (Plate I, figs. 4 and 5). The astral rays are conspicuous by their absence. The cytoplasm is either clear (Plate I, fig. 4) or may reveal fine granules (Plate I, figs. 3 and 5) which are the mitochondria. These are sorted out, more or less evenly, to the two daughter cells. It has not been possible to make out any accessory chromosome during the spermatogonial divisions.

The resting primary spermatocytes are definitely larger cells than the spermatogonia, their nuclei also being larger (Plate I, figs. 6 and 7). During the early prophases faintly staining spireme threads, with chromatin granules arranged on them, appear in the nuclei. In Plate I, fig. 6 the nucleus also reveals two rod-like structures which are most probably the accessory chromosomes. These, very often, fuse together to form a nucleolus-like body (Plate I, fig. 7). In the cytoplasm, as illustrated by figure 6, Plate I, there is a juxta-nuclear mass of fine greyish granules which are the mitochondria. One or more deeply staining granules, appreciably bigger than the mitochondria, can also be made out in this juxta-nuclear mass. These are the Golgi elements. As the spermatocytes grow the Golgi elements as well as the mitochondria become circum-nuclear in arrangement (Plate I, fig. 7). Some of the Golgi elements at this stage reveal a definite duplex structure with a chromophilic cortex and a chromophobic central core (Plate I, fig. 9). The spireme in figure 8, Plate I, appears to break up into chromosomes and simultaneously the cytoplasm reveals two sharply staining granules. These are the centrosomes which will now form the apices of the first meiotic spindle.

During the first meiotic division the chromosomes arrange themselves at the equator of the spindle which is a fibrillar structure with a sharply staining centrosome at each pole (Plate I, figs. 10 and 11). As the chromosomes move towards the respective poles a pair of distinct rod-like bodies can very often be seen passing undivided to one of the two daughter cells only (Plate I, figs. 10, 12 and 13). These are definitely the accessory chromosomes. The mitochondria and the Golgi elements are distributed almost evenly to the two daughter secondary spermatocytes (Plate I, figs. 10–14).

When the process of nuclear reconstruction is going on a number of granules appear at the equator of the dividing cell (Plate I, fig. 13). These granules constitute the so-called mid-body which later on becomes condensed to form a conspicuous deeply staining ring surrounding the remains of the spindle fibres. The latter persist for a long time in the form of a bridge connecting the two fully formed secondary spermatocytes (Plate I, fig. 14). It is important to note that some of the primary spermatocytes do not divide for a long time even after the nuclei of the two daughter secondary spermatocytes have been completely formed in them. One such example is illustrated in fig. 15, Plate I. The spindle and the conspicuous ring-like mid-body can be clearly seen on one side of the cell, the nuclei lying away from the poles of the spindle. This represents the well-known phenomenon of telokinesis.

Each resting secondary spermatocyte is almost similar to the primary, but it is definitely smaller than the latter (Plate I, fig. 16). The nucleus contains inside it a deeply staining nucleolus-like body which appears to be formed by the fusion of the accessory chromosomes. This is also confirmed by the fact that the peculiar nucleolus-like body is met with only in some of the secondary spermatocytes (presumably in one half of the total number). The remaining secondary spermatocytes which do not receive any accessory chromosome during the first meiotic division are conspicuous by the absence of this nucleolus-like body (Plate II, fig. 17).

Just before the second meiotic division the cytoplasm reveals a pair of sharply staining granules (Plate II, fig. 17). These are the centrosomes which are most probably formed by the division of the originally single centrosome. Each of these will now take its position at the respective pole of the second meiotic spindle. During this division even the accessory chromosomes divide equationally like the other ordinary chromosomes (Plate II, fig. 18). Mitochondria and the Golgi elements are again sorted out, more or less evenly, to the two spermatids thus formed (Plate II, figs. 18–23). The formation of the conspicuous ring-like mid-body can also be clearly seen in figs. 19–23, Plate II. It is again quite interesting to note here that the process of spermateleosis may proceed on without the complete separation of the daughter spermatids after the second meiotic division (Plate II, figs. 22–25). Very often, a cytoplasmic neck-like structure (spindle-remains) can be seen connecting the two fully formed spermatids (Plate II, figs. 23 and 24). After the complete separation of the daughter spermatids this neck-like structure degenerates. In the earliest spermatid as shown in fig. 26, Plate II, the chromosomal vesicles are seen fusing together to form the nucleus. The latter during the rest stage reveals a number of fine chromatin granules inside it (Plate II, fig. 27). The mitochondrial granules are distributed uniformly throughout the cytoplasm. A few prominent darkly staining Golgi granules can also be seen here and there. But these now have a distinct tendency to come together to form bigger granules (Plate II, figs. 22, 23, 26, 27 and 28). In figs. 27 and 28 can also be seen an extra-cellular axial filament which has grown out from the granular centrosome situated in the cytoplasm. This axial filament bears at its centre and the tip a bleb-like swelling which stains deeply.

One of the big Golgi granules now takes its position at the anterior pole of the nucleus (Plate II, fig. 29). This will later on grow to form a ring-like acrosome (Plate II, fig. 30). The remaining Golgi elements degenerate in the cytoplasm.

The centrosome in the meanwhile divides into a proximal and a distal portion (Plate II, fig. 29). The former which moves towards or over the nucleus becomes rod-like (Plate II, fig. 31). Both of these, however, remain connected through an intra-cellular axial filament. Ultimately the proximal rod-like centrosome takes its position underneath the nucleus just behind the acrosome (Plate II, fig. 32).

The nucleus which now becomes pear-shaped begins to stain deeply and this makes the task of differentiating the acrosome and the proxima

centrosome a little difficult (Plate II, figs. 32-33 and Plate III, figs. 34-35). The ring-like acrosome becomes triangular and at its apex is differentiated a darkly staining granule (Plate II, fig. 31 and Plate III, fig. 36). The pear-shaped nucleus at this stage becomes sinuous and by its peculiar movements it gradually spreads over the clear space vacated by it (Plate III, figs. 37–40).

As the spermatozoa are undergoing these changes the staining capacity of the nucleus again decreases. It, however, does not reveal any chromatin granule inside it (Plate III, figs. 37–40). Soon after, the sinuous nucleus along with the acrosome and the axial filament wriggles out of the cytoplasm containing the whole of the mitochondrial material and the degenerating Golgi elements (Plate III, figs. 41, 42, 45 and 46). These cytoplasmic masses discarded by the ripe spermatozoa later on degenerate completely.

The ripe sperm, therefore, does not seem to have any trace of the mitochondrial material (Plate III, figs. 43, 44, 47 and 48). The distal centrosome disappears from view in the ripe sperm after it has wriggled out of the cytoplasm (Plate III, figs. 47 and 48). The proximal centrosome also cannot be made out clearly as it completely fuses with the deeply staining nucleus of the ripe sperm. The axial filament increases in length and in the meanwhile its bleb-like swellings completely disappear. The deeply staining granule at the apex of the triangular acrosome appears to be connected with the nucleus by means of a lightly staining fibre (Plate III, figs. 41–44). But in smears all these details are often lost (Plate III, figs. 45–48).

The fully ripe spermatozoa in the lumen of the testis coil themselves in such a way that it becomes increasingly difficult to make out their different parts (Plate III, figs. 49–51).

Discussion

A. *Golgi Material.*

The Golgi elements could not be observed in the spermatogonia of *Plexippus paykulli*. They seem to make their appearance for the first time during the early spermatocyte stage just at the time when the juxtanuclear mass of mitochondrial granules begins to spread out in the cytoplasm. They are in the form of one or more deeply staining granules appreciably bigger than the mitochondria. As the spermatocytes grow the number of the Golgi elements increases and they also become circumnuclear in arrangement. Some of the Golgi elements now reveal a definite duplex structure with a chromophilic cortex and a chromophobic central core.

During the meiotic divisions the Golgi elements are sorted out, more or less evenly, to the daughter cells.

In the earliest spermatid there are a few prominent Golgi elements which have a distinct tendency to come together to form bigger granules. One of these big Golgi granules now takes its position at the anterior pole of the nucleus and thus directly forms the ring-like acrosome. The rest

of the Golgi elements remain in the cytoplasm which is completely discarded by the ripe sperm. As the spermatozoa ripen the ring-like acrosome becomes triangular and at its apex is now differentiated a deeply staining granule which is connected to the nucleus by means of a lightly staining fibre.

None of the previous workers on spider spermatogenesis has described any Golgi element. This is not surprising as most of the previous work is quite old and a few papers which can be considered as recent are concerned mainly with chromosomes.

Wagner (1896) described an apical body in the sperm of *Agalena*, and Bösenberg (1905) derived the apical body of the sperm in *Lycosa* from an idiozome vesicle. The latter, according to him, was formed by the disappearing spindle fibres. Wallace (1909), working on *Agalena nævia*, confirmed Bösenberg's account in every detail.

On the other hand I have clearly shown that the apical body described by these workers is really the acrosome and is formed by the fusion of a few Golgi elements.

My observations are strongly supported by the pioneer work of Montgomery (1911) who, working on the hemipteran *Euschistus*, demonstrated the direct origin of the acrosome from a body called the 'sphere' or the idiozome. This, as we now very well know, is nothing but the Golgi apparatus. Even Gatenby (1917) clearly proved in *Smerinthus* that the acrosome was directly formed by the running together of several acroblasts (Golgi elements).

Later in 1920, the late professor Doncaster and H. G. Cannon showed that the acrosome in the lice (*Pediculus corporis* and *Pediculus capitis*) was directly formed from a body which was considered to be the Golgi apparatus. This account was further confirmed by H. G. Cannon (1922) in the lice, *Hæmatopinus consobrinus*, *Hæmatopinus asini* and *Lignognathus piliferus*.

Bell (1929) also, working out the spermatogenesis of the dog, clearly demonstrated that the pro-acrosomic granules of Gatenby and Woodger (1921) were in reality the Golgi elements and not the secretory products of the Golgi dictyosomes which were merely artifacts. These Golgi granules later on directly fused to form the acrosome in the late spermatid.

Similar observations were made by Gobind Ram (1937) and Nath (1932 and 1942) in *Rhysida* (a scolopendrid) and *Paratelphusa* and its allies respectively.

In ticks also I have clearly shown that the Golgi elements which can be easily seen even in the living cells, directly fuse together in the spermatid to form the acrosome (Sharma, 1944).

B. *Mitochondria.*

In the earliest spermatogonia of *Plexippus paykulli*, the thin layer of cytoplasm does not reveal any granulation whatsoever. In some of the late spermatogonia, however, the cytoplasm on one side of the nucleus appears to be denser and it is now possible to make out a few greyish granules in this area. These are most probably the mitochondria. In

the earliest spermatocyte there is a juxta-nuclear mass of fine mitochondrial granules which begin to spread as the spermatocytes grow.

The sorting out of the mitochondrial granules during the meiotic divisions is almost even.

In the earliest spermatids the mitochondria are uniformly spread throughout the cytoplasm and they do not seem to change in any way during spermateleosis. Ultimately they are completely cast out as the ripe sperm wriggles out of the cytoplasm containing these granules.

This account is quite unique inasmuch as there seems to be no trace of any mitochondrial material in the ripe sperm. In every other animal except the doubtful case of *Peripatus* (Montgomery, 1912) all or most of the spermatid mitochondria form a sheath round either a part or nearly the whole length of the axial filament.

Even in some of the non-flagellate ripe sperms, e.g. the Decapod sperm (Nath, 1942) and the millipede sperm (Sharma, 1942) the mitochondria persist in the form of a clear vesicle which completely fits into the nuclear cup.

None of the previous workers on spider spermatogenesis has described any mitochondrial granule but most of them agree that the ripe sperm, consisting of the nucleus, apical body (acrosome) and the axial filament, wriggles out of the cytoplasm. I have also confirmed the above account and therefore it is quite obvious that the whole of the mitochondrial material which remains in the cytoplasm is also discarded by the ripe sperm.

Thus the absence of mitochondria in the ripe sperm of the spider (*Plexippus paykulli*) and *Peripatus* (Montgomery, 1912) clearly disproves the hereditary function attributed to them.

C. *Spermatogonial and Meiotic Divisions.*

Warren (1925 and later) has consistently described that in spiders the spermatogonial nuclei divide only by amitosis. But a glance at my figures will clearly show that there is typical mitosis during all the spermatogonial divisions. Even in the meiotic divisions no abnormality could be observed. The accessory chromosomes pass undivided only to one cell during the first or the reductional division and divide equationally during the second or the equational division. After each meiotic division, just before the two daughter cells are separated, a number of granules appear at the equator of the dividing cell. These granules constitute the so-called mid-body which later on becomes condensed to form a conspicuous deeply staining ring surrounding the remains of the spindle fibres. These persist for a long time in the form of a bridge connecting the two daughter cells. It is quite remarkable that the neck-like structure connecting the two sister spermatids may persist till the end of spermateleosis.

Similar observations have already been made by Wagner (1896), Bösenberg (1905) and Wallace (1909). Wagner called this neck-like structure as the 'connecting body'.

Carnoy (1885) was the earliest worker who described in detail the division of the male germ cells in a number of spiders, but, as I have

already pointed out, his work has no direct bearing on modern spermatogenetic processes, as he could not properly follow the sequence of changes during maturation.

Wagner (1896), working on *Agalena*, states that the spermatogonia do not divide by the ordinary method of karyokinesis; nor do they divide amitotically. I, therefore, fail to understand the exact method of division observed by him. He has also described a peculiar nucleolus in the growth period and also in the primary spermatocytic division. This, I believe is the fusion product of the accessory chromosomes. He, however, has not been able to trace this body correctly during the meiotic divisions.

Montgomery (1905) has followed in detail the history of the spermatocytes in *Lycosa*. According to him there is no rest stage at any period of the spermatocytic history. But in *Plexippus paykulli* I have clearly shown that well-marked rest stages occur not only in the spermatocytes (both primary and secondary) but also in the spermatids. The mode of division of the bivalent heterochromosome during the meiotic divisions was also not positively determined by Montgomery but it was suggested that it may behave like the other chromosomes, dividing first reductionally and then equationally. On the other hand, I have proved beyond doubt that the accessory chromosomes pass undivided to only one of the two daughter cells during the first meiotic division and divide equationally during the second.

Bösenberg's (1905) observations on *Lycosa* begin with the telophase of the second meiotic division and are mainly concerned with the transformation of the spermatid into the ripe sperm. He, like Wagner, has also mistaken the accessory chromosomes for a nucleolus which, according to him, disappears before the final maturation of the spermatid nucleus.

Berry (1906), working on *Epeira*, described in the telophase of the last spermatogonial division a chromosome which had no mate. This odd chromosome, according to her, passed undivided to only one pole during the first meiotic division. She could not identify this odd chromosome during the second meiotic division but she correctly conjectured that it divided equationally.

Wallace (1909) has very carefully described the behaviour of the accessory chromosomes in the spermatogenesis of *Agalena nævia* but I have not been able to confirm her statement that these accessory chromosomes persist and form an important part of the chromatin plate in one half of the spermatozoa.

Painter's (1914) description of the accessory chromosomes during the meiotic divisions in a number of spiders is also in conformity with my own observations.

D. *Centrosome and Axial filament.*

It will be recalled that I have described a conspicuous sharply staining centrosome at each pole of the spermatogonial and the meiotic spindles. In the earliest spermatid, to begin with, there is a single centrosome from which an extra-celluar axial filament is given out. This axial filament,

which is quite delicate, bears at its centre and the tip a deeply staining bleb-like swelling. Later on the single centrosome divides into a proximal and a distal portion. The former, which moves towards or sometimes over the nucleus, becomes rod-like. Both of them, however, still remain connected through an intra-celluar axial filament. As the spermatozoa ripen the distal centrosome disappears from view and the proximal, which now fuses with the underside of the nucleus, cannot also be made out very clearly. These observations of mine confirm the work of Wagner (1896), Bösenberg (1905) and Wallace (1909) who called the proximal centrosome as 'little tooth', 'middle piece' or the 'connecting piece' and the 'end knob' respectively.

In the ripe sperm the axial filament has considerably increased in length and its bleb-like swellings have also completely disappeared. Similar observations were also made by Bösenberg (1905) and Wallace (1909).

Gatenby (1917), working on the cytoplasmic inclusions of the germ cells in Lepidoptera, has also described large clavate structures at the tip of the outgrowing flagella. The flagellum, according to him, passes through the substance of the clubbed end and bears at its tip a dark spot (terminal body). What exactly is the function of such formations, I have not been able to ascertain but these may be the storehouses for nutritive matter as urged by Gatenby. Their later disappearance also seems to be correlated with the growth of the axial filament.

Summary

1. The spermatogenesis of the spider, *Plexippus paykulli* (Audouin), has been worked out in this paper.

2. Both the mitochondria and the Golgi elements are in the form of granules but the latter are appreciably bigger than the former. Some of the Golgi elements reveal a definite duplex structure.

3. During the division stages both the mitochondria and the Golgi elements are sorted out more or less evenly to the daughter cells.

4. The accessory chromosomes pass undivided to only one pole during the first or the reductional division and divide equationally during the second or the equational division.

5. In the spermatid the Golgi elements have a distinct tendency to come together to form bigger granules. One of these big Golgi granules directly forms the acrosome.

6. The single centrosome of the early spermatid divides into a proximal and a distal portion. The former which moves towards and sometimes over the nucleus becomes rod-like. In the ripe sperm it is difficult to make out any of these.

7. There is an extra-cellular as well as an intra-cellular axial filament. The bleb-like swellings on the former seem to be connected with its growth.

8. This investigation tends to disprove the hereditary function attributed to the mitochondria.

Explanation of Plates

All figures have been drawn with a camera lucida at the table level with Zeiss 4 eye piece and oil immersion objective giving a magnification of 1300 times.

All figures except figures 45 to 51 have been selected from sectioned material fixed in Flemming-without-acetic followed by 0·5% iron-hæma-

toxylin. Figures 45 to 51 are from smears fixed in Flemming-without-acetic diluted with an equal quantity of water and stained with 0·5% iron-hæmatoxylin.

A SIMPLE PROOF OF THE PRIME NUMBER THEOREM BASED ON SELBERG'S FORMULA

by

HANSRAJ GUPTA

A SIMPLE PROOF OF THE PRIME NUMBER THEOREM BASED ON SELBERG'S FORMULA

By Hansraj Gupta

(*Government College, Hoshiarpur*)

1. *Notations.*

In what follows, p_r denotes the rth prime; p, q run over primes; all small letters other than x denote positive integers unless stated otherwise; and x denotes a positive number. Moreover,

$$\theta(x) = \sum_{p \leqslant x} \log p, \quad \ldots \quad \ldots \quad \ldots \quad \ldots \quad (1)$$

and $\pi(x)$ denotes the number of primes not exceeding x.

2. The prime number theorem states that

$$\lim_{x \to \infty} \frac{\pi(x) \log x}{x} = 1;$$

or what is the same thing

$$\lim_{x \to \infty} \frac{\theta(x)}{x} = 1. \quad \ldots \quad \ldots \quad \ldots \quad \ldots \quad (2)$$

Using elementary methods, Selberg [1] has recently proved that

$$\sum_{p \leqslant x} (\log p)^2 + \sum_{pq \leqslant x} (\log p)(\log q) = 2x \log x + O(x).$$

This has led him to the important result:

$$U + L = 2, \quad \ldots \quad \ldots \quad \ldots \quad \ldots \quad (3)$$

where

$$U = \limsup_{x \to \infty} \frac{\theta(x)}{x}, \text{ and } L = \liminf_{x \to \infty} \frac{\theta(x)}{x}; \quad 0 < L \leqslant U.$$

Erdos and Selberg have obtained proofs of (2). Giving these in a recent paper,[2] Erdos has stated that Selberg has now a more direct proof of (2). This is, however, not available to me. I give here an extremely simple proof of (2) in the hope that it is different from Selberg's.

3. Consider the function $\{\theta(x)/x\}$ as x varies from 2 to ∞.

Let $p_r \leqslant x \leqslant p_{r+1} - \epsilon$,

where ϵ is a preassigned positive quantity however small.

Then since

$$\theta(x) = \theta(p_r),$$

therefore, $\{\theta(x)/x\}$ decreases continuously in this interval from $\{\theta(p_r)/p_r\}$ to $\{\theta(p_r)/(p_{r+1} - \epsilon)\}$.

In fact, $\{\theta(x)/x\}$ is a decreasing function except when x is a prime p. The curve

$$y = \theta(x)/x,$$

consists of portions of several hyperbolas running from one prime value of x to the next.

Now

$$U = \limsup_{x\to\infty} \{\theta(x)/x\} = \lim_{r\to\infty} \{\theta(p_r)/p_r\};$$

and

$$L = \liminf_{x\to\infty} \{\theta(x)/x\} = \lim_{r\to\infty} \{\theta(p_r)/(p_{r+1}-\epsilon)\},$$

$$= \lim_{r\to\infty} \{\theta(p_{r-1})/(p_r-\epsilon)\}.$$

Since

$$\frac{\theta(p_r)}{p_r} = \frac{\theta(p_{r-1})}{p_r} + \frac{\log p_r}{p_r},$$

$$< \frac{\theta(p_{r-1})}{p_r-\epsilon} + \frac{\log p_r}{p_r}.$$

Therefore,

$$U < L + \lim_{r\to\infty} \frac{\log p_r}{p_r}.$$

For every positive quantity δ however small, there is an r_0 such that for every $r \geqslant r_0$,

$$\frac{\log p_r}{p_r} \leqslant \delta.$$

Hence

$$L \leqslant U \leqslant L+\delta.$$

Since

$$L+U = 2,$$

we must have

$$L = U = 1.$$

This proves the theorem.

SOME OBSERVATIONS ON THE FORMATION OF THE HEN'S EGG WITH SPECIAL REFERENCE TO THE CHALAZIFEROUS LAYER AND THE CHALAZÆ*

By GANPATI PARSHAD SHARMA, M.Sc., Ph.D. (Panjab), Ph.D. (Edinburgh),
Animal Geneticist, Government Livestock Farm, Hissar, Panjab (I)

INTRODUCTION

In connection with investigations on the origin of blood and meat spots in the hen's egg opportunities arose to examine the ovaries and the oviducts of a number of Brown Leghorn birds killed from time to time at the Institute of Animal Genetics. Occasionally during such examinations immature eggs in various stages of formation from different levels of the oviduct were obtained. On opening some such eggs obtained from the uterus, no distinct structure resembling the normal twisted chalazæ, so conspicuous in a laid egg, could be found. These observations, in view of the existing confusion in the literature with regard to the formation of the chalaziferous layer and the chalazæ, led to a more extended and detailed study.

PREVIOUS WORK

Pearl and Curtis (1912) stated that the yolk during its passage through the magnum region of the oviduct acquired its chalazæ, chalaziferous layer, the dense albumen and also the inner layer of thin albumen. They were, however, doubtful about the existence of the last named layer. The outer layer of thin albumen, according to them, was added in the isthmus and the uterus by osmosis through the shell membranes already formed.

Surface (1912), in his description of the infundibulum, has described two kinds of epithelial cells lining the folds of the mucous membrane, namely ciliated and non-ciliated, the former being confined to the more superficial parts of the folds. The non-ciliated cells, according to him, line the deeper parts of the grooves between the folds and he regards these as glandular. Consequently the grooves they line are named by Surface as 'glandular grooves' or 'gland pouches'. He has also distinguished certain other non-ciliated cells in the region of mergence of the infundibulum into the magnum and has named these as 'unicellular glands'.

The presence of glands in the infundibulum led Surface to suggest that the chalazæ and the chalaziferous layer are secreted in this part of the oviduct.

Bradley (1928), while confirming Surface's statements, has added that Surface's 'unicellular glands' (his goblet cells) produce a secretion which,

* This work was carried out at the Institute of Animal Genetics, Edinburgh, during the period 1945–47 when the author worked there as Government of India Research Scholar.

'from its staining properties, must be looked upon as either mucin or something akin thereto'.

Richardson (1935) showed that the chalazæ and the chalaziferous layer were secreted in the caudal half of the infundibulum and he called this the 'chalaziferous region' of the oviduct.

Hansen (1933) found that in the magnum region of the oviduct only the very viscid layer of albumen was secreted and as he could not see any chalazæ till the egg had been in the uterus for some time he concluded that they were formed in the uterus. He also doubted the observation made by Pearl and Curtis (1912) with regard to the taking in of the outer layer of thin albumen as such through the shell membranes. According to him, this layer appears as the result of dilution of the dense albumen with the watery solution of salts diffusing through the shell membranes.

Conrad and Phillips (1938) confirmed Hansen's observations. According to them the layer of dense albumen next to yolk becomes more like a fluid before the egg reaches the uterus. There, due to the rotation of the albumen around the yolk, the mucin of this fluid-like gel is segregated to form the chalazæ and the chalaziferous layer, leaving a much more fluid inner thin albumen. They even produced this change experimentally.

Scott and Huang (1941), on the other hand, confirmed Richardson's observation on the formation of the chalaziferous layer. The chalazal formation was first noted by them in the small end of eggs removed from the posterior magnum.

Material and Methods

All eggs removed from the various levels of the oviduct were carefully examined for the nature of the albumen and also for the presence or absence of the chalazæ. The yolks were then carefully separated from the albumen and after being agitated for a few minutes in 0·8% normal saline, were immediately fixed in Formol Saline. The dehydration was done as usual by passing the specimens through up-graded alcohols and cedarwood oil was used as a clearing agent. The yolks were embedded as such but for sectioning small pieces were cut from the two poles and also from the sides.

Sections were cut 5-6μ thick and stained with Delafield's hæmatoxylin and Eosin technique. Thionin blue was also used to differentiate the chalaziferous layer from the vitelline membrane.

Observations

A casual observation of all the eggs removed from the anterior and the mid-magnum region of the oviduct shows the yolk to be surrounded by a very dense envelope of albumen only. No definite chalazæ can be made out at this stage. Figures 1 and 2 are the photo-micrographs of sections of such yolks from the anterior and the mid-magnum region respectively. These clearly reveal two membranes surrounding the yolk. The outer of these is the chalaziferous layer and the inner the vitelline membrane. Both the layers can be easily seen even in preparations stained with Delafield's hæmatoxylin followed by Eosin. Thionin blue, however, gives the best differential results, staining the chalaziferous layer a purplish pink and the

vitelline membrane a pale blue. It is very difficult, however, to preserve this stain during dehydration.

Apparently the eggs from the posterior magnum region of the oviduct are also similar to those described above. However, on closer observation a faint whitish cloud can very often be observed near that pole of the yolk which is towards the isthmus. Figure 3 represents the section of such a yolk from the polar region. Here, in addition to the two membranes covering the yolk one can also see a cluster of fibres outside the chalaziferous layer. These fibres, which constitute the whitish clouds referred to above, stain with all the mucin stains exactly like those of the chalaziferous layer. These are, therefore, nothing but mucin fibres and are the precursors of the chalazæ. Simultaneously with the appearance of the mucin fibres the inner layer of thin albumen also becomes visible. It can be made to flow out by puncturing the envelope of thick albumen. Very often the mucin fibres forming the faint whitish clouds also flow out with it.

Figure 4 is a section of that pole of a yolk which was inside the isthmus. When this egg was removed from the oviduct only approximately one half of it was covered by a thin shell membrane while the other half, not yet within the isthmus, was without it. This section has been particularly selected to show the mucin fibres joining the chalaziferous layer at two points. These represent the bases of the chalazal core. Even in laid eggs the bases of the chalazæ can very often be seen to form cap-like structures at the two poles of the yolk.

In the isthmian eggs faint whitish clouds can be made out at both poles of the yolk. The inner layer of thin albumen is also present in these eggs. The thick albumen is still quite dense and no definite outer layer of thin albumen can be seen.

Figure 5 represents the contents of a shelled egg from the uterus. Here the outer layer of thin albumen is also quite conspicuous. The chalaza towards the narrower end of the egg is larger than that in the other. The normal twisting of the chalazæ is still not very distinct.

Discussion

According to Conrad and Phillips (1938) the layer of dense albumen next to the yolk becomes more like a fluid before the egg reaches the uterus. There, due to the rotation of the albumen around the yolk, the mucin of this fluid-like gel is segregated to form the chalaziferous layer and the chalazæ. On the other hand, it has been clearly shown in the present study that the chalaziferous layer is to be found even in eggs removed from the anterior magnum region.

As early as 1898 Mitrophanow described the envelope of yolk as consisting of two layers—an internal or the vitelline membrane and an external or the albuminous layer. The presence of blood spots in between the two layers led Mitrophanow to suggest that the external albuminous layer (chalaziferous layer) was secreted in the oviduct.

Lécaillon (1910, *a* and *b*) thought that the external layer was completed before the egg reached the oviduct but later on (1910 *c*) he modified his view in favour of that of Mitrophanow (1898).

Surface (1912), Bradley (1928), Richardson (1935) and Scott and Huang (1941) have all presented evidence that the chalaziferous layer is secreted in the posterior portion of the infundibulum to which the name 'chalaziferous region' of the oviduct was given by Richardson (1935). It has not been possible to confirm their observations directly as eggs from the 'chalaziferous region' were not obtained. However, from the present observations and in the light of the previous work it can be concluded that this layer is secreted in the posterior portion of the infundibulum, the true chalaziferous region'.

It would not be out of place to mention here the work of Burmester and Card (1939). They removed sections, 2–7 cm. long, from the 'chalaziferous region' of the oviduct and reported that such resection was conducive to the formation of dwarf or yolkless eggs. It could be suggested that as no chalaziferous layer was secreted, due to the absence of this particular region, the delicate vitelline membrane could not remain intact while passing through the narrow oviduct. The yolk, thus set free, was either pushed back into the body cavity perhaps by antiperistalsis or was included in the dwarf eggs.

As already pointed out by Burmester and Card (1939) that the resection of the 'chalaziferous region' did not have any significant effect in decreasing the weight of the chalazæ, Scott and Huang (1941) also showed that the quantity of mucin secreted in that region could not possibly form the chalazæ. These are, according to them, formed by the mucin secreted in the magnum region. These observations have been confirmed in the present study. Figures 3 and 4 show clearly that the mucin fibres secreted in the magnum region are added on gradually to the chalaziferous layer at the two poles of the yolk and these constitute the material for the chalazæ. The normal twisting of the chalazæ (Almquist, 1936) is seen only after the egg has been in the uterus for some time. This results from the rotation of the thick albumen around the yolk as already proved experimentally by Conrad and Phillips (1938). It may also be pointed out here that in the miniature eggs where, due to the absence of the normal yolk, the thick albumen does not find anything to rotate around, the normal chalazæ are absent.

It is now a well established fact that the inner layer of thin albumen is present long before the egg reaches the uterus. Almquist (1936) suggests that it probably results from syneresis of a part of the dense albumen as dilution of this with water or a watery solution cannot account for the formation of this layer. To support his view he also quotes Almquist and Lorenz (1933) and Romanoff (1929), according to whom, the inner layer of thin albumen has a higher solids content than the dense albumen or the outer layer of thin albumen. The chalaziferous layer, according to them, has even a still higher solids content.

Conrad and Phillips (1938) state that the dense albumen just near the yolk becomes more like a fluid before the egg reaches the uterus. This results not from the chemical destruction of mucin but by the breaking down of the gel structure. They could not, however, decide whether this

change was brought about by some mechanical action of the oviduct or by the presence of chemical agents.

Scott and Huang (1941) noted that the staining reaction of the layer nearest the yolk changed gradually during egg formation. They, therefore, ascribed this change (from the gel to the suspension of mucin fibres) to the presence of some chemical agent.

It is also quite possible that the inner layer of thin albumen may be secreted as such by the anterior magnum region of the oviduct as would appear from the work of Asmundson and Burmester (1936). The resection of 7, 8 or 10 cm. long parts from the anterior portion of the albumen tube resulted in the reduction of liquid albumen while the amount and percentage of firm albumen did not show any significant change. The work of Cole (1937 and 1938) also points towards the same conclusion. He suggests that the number and distribution of the mucin fibres determine the condition of a particular sample of albumen. He further states that the height of the goblet cells which secrete the mucin fibres averages 11·4μ in the anterior portion of the magnum, 15·7μ in the middle region, 30μ in the posterior region and reaches a maximum of 33·9μ at the junction with the isthmus.

There is no doubt that the outer layer of thin albumen appears only after the shell membranes have been formed, but the method of its appearance has been the subject of much discussion.

According to Pearl and Curtis (1912), the egg, during its stay in the isthmus and the uterus, receives its outer layer of thin albumen by a process of osmosis through the shell membranes. McNally (1934), by a study of the amount of the various proteins in mature and immature eggs, found that the former contained more of ovoglobulin than the latter. This, according to him, is taken in through the shell membranes.

Hansen (1933) doubted the observation of Pearl and Curtis (1912) as, according to him, the shell membranes must be impermeable to albumen. This doubt originated from the non-diffusion of albumen when a shell-less egg was placed in water. He, therefore, concludes that only the watery solution of salts is taken in after the shell membranes have been formed. Indirect evidence presented by Asmundson and Jervis (1933) and Asmundson and Burmester (1936 and 1938) is also in support of Hansen's view that no appreciable amount of protein enters the egg after the formation of the shell membranes.

Hughes and Scott (1936) found that after an egg was laid the greatest increase in ovoglobulin was in the inner layer of thin albumen while, according to McNally (1934), it should be in the outer layer of thin albumen. They suggest that the increase in the amount of ovoglobulin is due to a change in the solubility of the egg white proteins.

Similarly Scott, Hughes and Warren (1937) have presented evidence to show that proteins would not pass from the uterine secretion of low protein concentration into the egg white of high protein concentration through the shell membranes.

Beadle, Conrad and Scott (1938) have found that the uterine secretion is not an albuminous solution like that which forms the outer layer of thin albumen in a laid egg. The uterine secretion, according to them, is a

mineral solution made up of sodium, calcium and potassium in the form of chlorides and bicarbonates. From an analysis of uterine and laid eggs they have concluded that the principal additions to the albumen of an egg, while it is in the uterus, are water, potassium and bicarbonate ions with smaller amounts of sodium and chloride ions.

That water is added to the egg, while it passes through the isthmus and the anterior uterus, has also been conclusively proved by Burmester (1940).

It can, therefore, be safely concluded, as has already been suggested by Conrad and Scott (1938), that the outer layer of thin albumen is formed by the inflow of uterine fluid. As the uterine secretion diffuses into the egg the soluble proteins of the dense albumen come out and increase the solids content of the outer liquid layer.

Summary

1. The chalaziferous layer is secreted in the posterior portion of the infundibulum, the so-called 'chalaziferous region' of the oviduct.

2. In eggs removed from the posterior magnum a faint whitish cloud of mucin fibres can often be observed in that end of the egg which is towards the isthmus. These mucin fibres are the precursors of the chalaza.

3. Simultaneously with the appearance of the mucin fibres the inner layer of thin albumen also becomes visible.

4. In the isthmian eggs faint whitish clouds of mucin fibres can be seen at both poles of the yolk.

5. The normal twisting of the chalazæ is observed only after the egg has been in the uterus for some time. This takes place due to the rotation of the thick albumen round the yolk.

6. The outer layer of thin albumen becomes distinct only in the uterus.

7. The mode of formation of the inner and the outer layer of thin albumen is discussed.

Acknowledgments

I must take this opportunity to thank Dr. A. W. Greenwood, D.Sc., F.R.S.E., Director, Poultry Research Centre, Edinburgh, for very kindly going through the manuscript of this paper. Thanks are also due to Mr. G. R. Knight for taking the photo-micrographs.

ANATOMY OF *PARAMPHISTOMUM (CAULIORCHIS) CRASSUM*

By N. K. Gupta, *Government College, Hoshiarpur*

Acknowledgments

I am deeply grateful to Professor Dewan Anand Kumar, M.A. (Cantab.), Vice-Chancellor of the East Panjab University, under whose supervision this work was carried out at Lahore (1940–42), for his valuable suggestions, helpful criticism and sympathetic interest in the completion of this study. I am also indebted to the late Professor Dr. George Matthai, Sc.D. (Cantab.), I.E.S., for his encouragement and provision of facilities in the laboratory to carry on this work. My thanks are also due to Dr. Vishwa Nath, M.Sc., Ph.D. (Cantab.), F.N.I., P.E.S. (I), for editing the paper.

Introduction

In India, where hygienic standards are low, helminths constitute a very real menace to the health of man and his live stock. For a long time, the importance of parasitic worms was not recognized and the serious damage to health caused by them was not properly appreciated. This was perhaps largely due to the fact that the common symptoms of helminthiasis are not always sufficiently spectacular to attract immediate attention. In recent years, however, there has been a gradual realization of the importance of worms as a factor in the health of man and animals.

Prevention is always the best method of control of worm infestations. Helminths do not multiply within the body of their hosts and prevention in helminthology is largely a matter of biology of the parasite. A detailed knowledge of the features of taxonomy, bionomics, anatomy and biology must necessarily be the first pre-requisite in the formulation of effective control measures against them. A considerable amount of work has been done along these lines during the last two decades and useful information on the occurrence of worms in Indian animals is available. However, details of the anatomy and bionomics of some of the common parasites of economic importance still need further investigations. It was at the kind suggestion of Dr. George Matthai that the investigations on the anatomy of *Paramphistomum* (*Cauliorchis*) *crassum* were undertaken.

Material and Technique

Material.—The material for these studies was collected during 1941 from cattle slaughtered in the Municipal abattoir at Lahore. A large collection of Amphistomes was made, out of which five species were selected for detailed study. These are:—

(*a*) *Paramphistomum* (*Cauliorchis*) *crassum* Stiles and Goldberger (1910).

(*b*) *Paramphistomum bathycotyle* Fischoeder (1901).

(*c*) *Paramphistomum dicranocoelium* Fischoeder (1901).

(*d*) *Paramphistomum cervi* Zeder (1790).

(*e*) *Paramphistomum explanatum* Creplin (1847).

The account of only the first species is being published for the present

Technique.—The methods employed in the study of amphistomes are mostly those ordinarily used in Helminthology. For the study of the excretory system special methods of impregnation were used.

Fukui (1929) suggested a method for the study of the excretory system in Amphistomes. It consists in fixing flattened specimens in the acetic sublimate solution for 12 hours and then washing them in running water for 10–20 minutes. After this the specimens are treated with 1–5% aqueous solution of potassium hydroxide, and dehydrated and cleared in xylol or turpentine. The excretory system shows itself prominently in black. The whole mounts of the specimens thus prepared can be studied at leisure. The author has, however, deviated slightly from Fukui's procedure. Only 1% solution of KOH was used instead of the higher strength suggested by Fukui and the specimens kept in the solution for 1–2 hours only. If higher strengths of KOH are used, it materially damages the specimens, possibly due to higher temperatures of our laboratory.

Hypodermic injection of methylene blue in living worms for staining the excretory system was tried with unsatisfactory results.

Amphistomes stain readily and a wide choice of stains is available, though certain stains may give better results with one species than with others. In order to get sharp differentiation it is better to overstain the specimens in dilute solution of the stain and then to differentiate them. Of the several stains borax-carmine, Mayer's haemalum, Delafield's haematoxylin, acetic-acid-alum carmine and Mayer's carm-alum as modified by Gower (1939) were employed by the author, the last one gave by far the best results.

Mayer's carm-alum as modified by Gower is prepared in the following way:—

(*a*) 10 grms. of carmine is added to 100 c.c. of glacial acetic acid and stirred well. The mixture is filtered and the filtrate after drying is called *acidified carmine.*

(*b*) One grm. of acidified carmine and 10 grms. of alum are dissolved in 200 c.c. of distilled water. The stain can be used when required but to prevent any growth of mould a crystal of thymol is added to it. For the differentiation of stained specimens, Mayer's chlorinated alcohol is preferable to 70% acid alcohol. It is prepared by passing chlorine through 70% alcohol. Preserved and flattened specimens are first brought down to water and kept in the stain overnight or even longer depending upon the thickness of the specimen. They are then washed in distilled water, differentiated in chlorinated alcohol and mounted in the usual way.

For section cutting, specimens were embedded by the usual ordinary and double embedding methods. The material after clearing was embedded overnight in 60°C. paraffin wax in an electric bath for ten to twelve hours. Serial sections 8–12 μ thick were cut.

No reliable methods are available for the study of the lymphatic and nervous systems of amphistomes in entire mounts. The excretory and lymphatic systems were studied in living specimens as far as possible. Reconstructions from serial sections were used to confirm the results of the study of these systems in living specimens, and also for the study of the nervous system. Golgi's method failed to make the nervous system clear in whole mounts. Incidentally, a specimen of *Paramphistomum* (*Cauliorchis*) *crassum* which was impregnated to bring out excretory system also revealed the nervous system.

A brief survey of the systems of classification of Amphistomes.

The trematodes with an opening at either end were all referred to as Amphistoma by Rudolphi in 1801. In 1809, he divided 'Amphistoma' into two groups 'Capite discreto' and 'Capite continuo'. Ten years later, Nitsch proposed the genus *Holostomum* for the former group and retained the name *Amphistomum* for the latter. Monticelli (1888) created the family Amphistomidæ, but four years later separated *Gastrodiscus* Leuckart (1877) from the rest and created the sub-family Gastrodiscinae. Fischoeder (1901), finding the name *Amphistoma* preoccupied, proposed the genus *Paramphistomum* and erected the family Paramphistomidae. The family Paramphistomidae has received considerable attention of subsequent workers, several of whom, notably, Fischoeder (1901–1904) Stiles and Goldberger (1910), Maplestone (1923), Stunkard (1925), Fukui (1929), Travassos (1934), Southwell and Kirshner (1937), and Nasmark (1937) have tried to formulate a sound scheme of classification. Nevertheless, opinions differ very widely in regard to the status of the family and its sub-divisions.

Anatomy of

Paramphistomum (*Cauliorchis*) *crassum* Stiles and Goldberger (1910).

Host—*Bos bubalis*.

Habitat—*Rumen*.

Locality—Lahore (Punjab).

External characters.—Live worm is light pink in colour, the extremities being slightly deeper. It has a glassy shine due to mucus. It is conical in shape, tapering postero-anteriorly (Plate I, fig. 1).

The worm may be slightly flexed ventrally due to the contraction. The preserved unpressed specimens measure from 6·1–6·46 mm. in length, 4·18–4·83 mm. in breadth in the middle region, the maximum breadth being 4·27–5·11 mm. The flattened preparations vary from 11·25–13·57 mm. in length, 4·42–5·58 mm. in breadth in the middle region, the maximum breadth being 5·48–6·78 mm.

The outer general surface appears wrinkled owing to transverse grooves formed as a result of contraction. The body is free from hooks and spines

but on its ventral and dorsal surfaces there are small conical papillae which can be best observed in sagittal sections. The mouth is placed at the anterior end of the worm. The genital pore is situated on a slightly raised area in the median line on ventral side of the body (Plate I, fig. 1). In a specimen of average size, it is situated at a distance of 1·395 mm. from the oral aperture and 4·371 mm. from the acetabular. The excretory pore lies in the lower half of the dorsal region. The opening of the Laurer's canal is situated a little posterior to the excretory pore, but both these pores can be seen in sagittal sections only (vide infra). The oral sucker (interpreted by some authors as pharynx) is situated at the anterior end. The acetabulum is a large muscular organ at the posterior end of the body. The acetabular opening, 1·4×1·6 mm. in size, is directed terminally in the natural condition, but in preserved forms it becomes somewhat subventral or ventral in position. It is difficult to measure its length and breadth, as on contraction the opening gets covered by the proximate folds of the body (Plate I, fig. 1).

The Body-wall.—The body-wall (Plate II, fig. 9) consists of (*a*) the cuticle, (*b*) the subcuticle, (*c*) the muscular layer, and (*d*) the layer of subcuticular cells. The cuticle is the external layer measuring 0·024 mm. in thickness, and is beset with small conical papillae both on the dorsal and the ventral sides of the body. The cuticle appears striated in sections. Internally it extends up to oesophagus, ductus ejaculatorius, metraterm, Laurer's canal, excretory canal and the acetabular lumen. The subcuticle is broader than the cuticle, and runs all round the body, and measures about 0·032 mm. in thickness. It is traversed by strands connecting the subcuticular cells and the cuticle and the presence of these makes it striated. This layer does not pick up any stain. The subcuticle is followed by a layer of circular muscle fibres and four to five bands of longitudinal muscles. Oblique muscle fibres are present in groups in between the clusters of subcuticular cells.

The Muscles and Parenchyma.—There are two pairs of inner and outer retractor muscles, which extend from the acetabulum up to the oral sucker (Plate III, fig. 14). The peripheral muscle bands are also in two pairs which run longitudinally on the lateral sides of the worm. There is another pair of longitudinal muscle bands, dorsal to the subcuticular cells. The dorso-ventral muscle fibres running between the two main longitudinal muscle bands are also present.

The body parenchymatous cells are irregular in outline due to the contraction of the body. The cells below the integument are narrower than those surrounding the internal organs. At some places the walls of the adjoining cells become fused.

The Digestive System.—The digestive system (Plate I, fig. 2) consists of the mouth, the oral sucker, the oesophagus and the intestinal caeca. The mouth is a small circular narrow aperture in the centre of the oral sucker and measures 0·36–0·4 mm. in diameter. The oral sucker measures 1·35–1·95 mm.×1·48–1·86 mm.; in sections it is from 1·4–1·65 mm. in length, from 1·05–1·24 mm. in thickness and 1·4 mm. in breadth. It lies in the peri-suctorial cavity and is attached to the body parenchyma at its oral and basal ends, and by delicate mesenterial bands to both the dorsal and the ventral

sides. The lumen of the oral sucker is spindle-shaped having its either side lined by 13 to 17 small conical papillae. It measures from 1·4–1·69 mm. in length and 0·234 mm. in dorso-ventral diameter.

The oesophagus is a thin tube arising from the basal portion of the oral sucker and is continuous with it. It bifurcates into two intestinal caeca which run laterally. On reaching the ventro-lateral aspect of the body, they change their course and each caecum then runs posteriorly in a coil towards the acetabulum along the body-wall. The caeca end blindly, the right caecum is slightly longer than the left and terminates close to the middle of the acetabulum. The blind ends of the caeca are a little dilated (Plate I, fig. 2). The oesophagus is lined with cuticle which is co-extensive with the cuticle of the lumen of the oral sucker. Round the cuticle is a layer of circular muscle fibres and next to this is a thin layer of longitudinal muscle fibres. Subcuticular cells are present all round the oesophagus. The caeca are lined by ciliated columnar epithelium, which is followed by circular and longitudinal muscle fibres (Plate I, fig. 3; Plate IV, fig. 20).

The Suckers.—There are two suckers: the oral sucker and the acetabulum. The oral sucker is a globular muscular organ situated anteriorly (Plate I, fig. 2). It measures from 1·35–1·95×1·48–1·86 mm. in whole mounts and in sections 1·65×1·24 mm. It is composed of cuticle, muscles, parenchymatous cells, subcuticular cells, nerve cells and limiting membrane (Plate II, fig. 7; Plate IV, fig. 17). The cuticle is the extension of the outer cuticle and forms a thin lining to the lumen of the oral sucker.

There are several layers of muscles in the oral sucker. Immediately surrounding the cuticle is a layer of interior circular muscle fibres which are present in bands. It is followed by a layer of interior longitudinal muscle fibres, which are crossed dorsally with some oblique muscle fibres. Next to them, there is some more thick crossing of the same fibres (Plate II, fig. 7). A little further is a layer of poorly developed middle longitudinal and exterior circular muscle fibres. The former layer makes a curve as it extends towards the oral and aboral poles. The limiting membrane forms the outer lining of the oral sucker and underneath it is a layer of exterior longitudinal muscle fibres. Apart from these there are radial muscle fibres, present in bands, extending from the cuticle up to the limiting membrane. Basally there are a few bands of circular muscle fibres, which are feebly developed. In addition to the basal circular muscles, there are 3–4 bands of circular muscle fibres, known as the posterior sphincter muscles (Plate IV, fig. 17).

The parenchymatous cells of the oral sucker are of a smaller size than the body parenchymatous cells and those of the acetabulum. They are more closely packed up in the outer and inner regions.

There are two layers of subcuticular cells, the first consisting of scattered cells is just below the crossing of longitudinal and oblique muscle fibres; while the second layer, slightly apart, has its cells lying in compact groups (Plate II, fig. 7). Besides these there are a few more cells scattered all over its surface. The subcuticular cells are deeply stained with haematoxylin.

In well-differentiated serial sections, scattered nerve cells are clearly visible in the upper region of the oral sucker (Plate II, fig. 7).

The ratio between the length of the oral sucker and the length of the body is 1 : 9·1–1 : 10·5 in flattened specimens and 1 : 4·2–1 : 4·6 in sagittal sections.

The acetabulum is a strong muscular organ placed at posterior extremity of the body. It has a small opening as compared to its large size. The acetabulum measures 2·95–3·48 × 2·9–3·34 mm. and its opening 1·02 1·58 × 1·11–1·76 mm. In transverse sections the dorsal wall measures 0·918–0·99 mm., the lateral wall 0·684 mm. and the ventral wall 0·342 mm. in thickness. The opening of the acetabulum is irregular due to the adjacent folds of the body surface. The acetabulum is attached to the body parenchyma by mesenterial bands. Histologically, it is composed of the cuticle, the muscles, parenchymatous cells, subcuticular cells, the nerve cells and the limiting membrane.

In this there are oblique, circular, longitudinal and radial muscle fibres. Underneath the cuticle there is a meshwork of oblique muscle fibres. On the dorsal side of the oblique muscle fibres are the circular muscle fibres, which are arranged in bands and are better developed on the lateral sides. These lateral circular muscles are called the dorsal exterior circular, dorsal interior circular, ventral exterior circular and ventral interior circular. The dorsal exterior circular muscle fibres are in 25 bands, the dorsal interior circular muscle fibres in 43, the ventral exterior circular muscle fibres in 18 and the ventral interior circular muscle fibres in 55. Underneath the limiting membrane there are bands of longitudinal muscle fibres. The radial muscles are many, and extend from the cuticle to the limiting membrane (Plate III, figs. 12, 16).

Parenchymatous cells are, as compared to those of the body, smaller in size and are present in between the muscle fibres. A little away from the cuticle, there are subcuticular cells present in groups (Plate III, figs. 12, 16). Large-sized nerve cells are found dorsal to the layer of subcuticular cells.

The ratio between the diameter of the acetabulum and the length of the body is 1 : 4·1 in flattened specimens and 1 : 1·9–1 : 2·3 in sagittal and longitudinal sections.

The Excretory System.—There are two main excretory canals each running along either side of the oral sucker and the intestinal caecum. Posteriorly near the acetabulum, the two canals bend inwards and meet to form a prominent excretory vesicle (Plate III, fig. 15). Dorsal to the vas deferens lies a small vesicle, which is connected to the main excretory canals by two connecting canals. From the dorsal side of the excretory vesicle arises a canal, which opens on the dorso-median line of the body. The excretory pore lies just above the opening of the Laurer's canal (Plate IV, figs. 18, 21) in level with the excretory vesicle.

The Lymphatic System.—For a long time the lymphatic system received little attention on account of the difficulty in tracing it, specially in thick forms, and it was therefore considered to be of no taxonomic importance. Van Beneden (1859), Walter (1893), and Looss (1896) considered it as a part of excretory system or excretory system itself. Looss (1902) was the first to recognize the lymphatic system as independent of the excretory system and called it 'Lymphgefass system'. He made it definitely clear

that the lymph system had no connection with the excretory system and the lymph vessels ended blindly. Maccallum (1905) described the lymph vessels as 'endothelial tubes' and thought that they communicated with the excretory channels. Stiles and Goldberger (1910), while describing the species of Paramphistomidæ made no mention of it. In 1912, Looss showed its importance in taxonomy. Stunkard in 1917 described the lymphatic system in *Allassostoma*. Maplestone (1923) also ignored this system and disposed it off as too complicated for practical purposes. Stunkard in 1925 again supported Looss' view on the lymphatic system. Fukui in 1929 described it in his general description of Amphistoma, and Willey (1930) made a detailed study of this system in digenetic trematodes.

The lymphatic system in the species under investigation was studied in living specimens but its details could not be worked out owing to the thickness of the body-wall. Attempts were made to impregnate this system with corrosive sublimate without much success. It has been possible to study the system only from the longitudinal serial sections of the worm. The two main lymph vessels run longitudinally in the body along the intestinal caeca throughout the greater portion of the course (Plate II, fig. 11). They give off a large number of lateral branches, which encircle the various organs without directly communicating with them. Anteriorly they surround the oral sucker and posteriorly the acetabulum. In sections the lymph vessels can be easily differentiated from excretory vessels by the presence of granules in the former. The wall of a lymph vessel is membranous. The close association of the lymph vessels and their branches with the intestinal caeca indicates that they carry the digested food from them to the various organs of the body.

The Nervous System.—A little posterior to the oral sucker there is a mass of nervous tissue, the brain, lying over the oesophagus. Three pairs of nerves arise from its anterior end and three pairs from the posterior end (Plate III, fig. 13).

The Reproductive System.—All amphistomes are hermaphrodite. The male genital system (Plate I, fig. 2) consists of testes, vasa efferentia, vas deferens and ductus ejaculatorius. A pair of testes is situated diagonally in the middle of the body in between the intestinal caeca. They are multilobed giving the appearance of small cauliflowers and show a great affinity for the stains. In flattened preparations the anterior testis is 0·74–1·3 × 1·11 mm. in dimensions; the posterior testis measures 0·93–1·11 × 1·11–1·58 mm. In sagittal sections the anterior testis measures 1·332 mm. transversely and 0·612 mm. longitudinally. The posterior testis measures 0·99 mm. transversely and 0·612 mm. longitudinally (Plate II, fig. 8; Plate IV, fig. 21). In longitudinal sections the anterior testis measures 0·4 mm. transversely, 0·28 mm. longitudinally and the posterior testis measures 0·48 × 0·28 mm. But the testes are placed above the region of the acetabulum and are surrounded by lymph vessels. Arising from the lateral side of each testis is a vas efferens and the two vasa efferentia unite in front of the anterior testis, to form the vas deferens. Its first part is known as the vesicula seminalis, the second as pars-musculosa and the last as pars-prostatica, which is continued into the ductus ejaculatorius. The short and coiled vesicula seminalis

is continued into the pars-musculosa, which is more convoluted. The pars-musculosa is strongly developed in this species. The duct at either end of the pars-musculosa is narrowed. These narrow parts, one between the vesicula seminalis and the pars-musculosa and the other between pars-musculosa and pars-prostatica, are known as pars-intermedia. The pars-musculosa beyond the pars-intermedia is continued as the pars-prostatica. This is a straight tube and is enveloped by the prostate gland cells (Plate I, fig. 5; Plate II, fig. 8). As the pars-prostatica emerges out of the prostate gland cells, it gets considerably reduced in calibre and is called the ductus ejaculatorius. The latter unites with the terminal portion of the uterus and leads into a delicate chamber called the ductus hermaphroditicus (Plate II, fig. 10), which opens out through the genital papilla. The walls of the genital papilla are studded with sphincter papillae (Plate II, fig. 10). The genital atrium is strengthened by the genital-atrial-radial muscles. Besides these muscles there are genital sphincter muscles which are extremely small. The ventral atrium is without such muscles and in itself is not quite distinct. The male genital ducts throughout their course are surrounded by two layers of muscle fibres, an inner circular layer and an outer longitudinal. These are particularly well developed in the region of pars-musculosa (Plate IV, figs. 19, 21).

The female genital system (Plate I, figs. 2, 4) consists of the ovary, the oviduct, the Laurer's canal, the vitellaria and their ducts, Mehlis' glands, the ootype, the uterus and the metraterm. The ovary is situated on the right side of the post-testicular region of the body in front of acetabulum. It is more or less spherical in shape and measures 0·42–0·54 × 0·3–0·35 mm. It is surrounded by lymph vessels. The oviduct emerges from the posterior border of the ovary. After a short free course it enters the Mehlis' gland complex and comes out as the uterus. The Laurer's canal arises from the oviduct at a place where the latter enters Mehlis' gland complex. Then it runs laterally and after crossing the excretory vesicle, opens on the right side of the median line, a little posterior to the excretory pore (Plate I, fig. 4; Plate IV, fig. 18).

The vitellaria are feebly developed. In gravid worms they are prominently seen extending from the sides of the oral sucker along the intestinal caeca up to the middle of the outer sides of the acetabulum. The cells forming the follicles are well differentiated being surrounded by a thin structureless membrane. The nuclei of vitellaria are conspicuous and stain deeply with haematoxylin. The nucleoli pick up a still deeper stain.

The Mehlis' gland complex, like the ovary, is a compact structure and is visible even to the naked eye in flattened specimens. Typically it is more or less in the form of an oval, the long axis being directed transversely. It measures 0·36 × 0·45 mm., and is composed of a large number of cells aggregated together and not enclosed within a membrane. Each cell is club-shaped, radiating out from the ootype, into which it empties itself by a narrow drawn out duct (Plate I, fig. 6; Plate IV, fig. 18). The ootype is a rounded structure, measuring 0·05 × 0·05 mm. It receives a duct of the yolk reservoir, which is formed by the two vitelline ducts, one from each side of the vitellaria.

The uterus winds its way towards the left side of the ovary forming coils, and then proceeds anteriorly dorsal to the testes and opens into the ductus hermaphroditicus through a metraterm, just beneath the ductus ejaculatorius (Plate I, fig. 5). The ductus hermaphroditicus is formed by the union of ductus ejaculatorius and the metraterm, and opens at the tip of the papilla. The genital pore lies in the ventromedian line, just below the bifurcation of the intestinal caeca (Plate I, fig. 2). The eggs, in the specimens sectioned, measure $0{\cdot}104 \times 0{\cdot}06$ mm.

Summary of Conclusions

(*a*) *Paramphistomum* (*Cauliorchis*) *crassum* has been retained as a valid species and is not a synonym of *P. explanatum* Creplin (1847).

The following peculiarities have been observed:—

(*b*) The Body-wall:

Cuticle is thick and papillated.

(*c*) The Muscles:

There are two pairs of retractor muscles which extend from the acetabulum to the oral sucker.

(*d*) The Digestive System:

Intestinal caeca are coiled.

(*e*) The Oral Sucker:

(i) Its lumen is lined with small conical papillæ.

(ii) Interior circular muscles are present in distinct bands.

(iii) Interior longitudinal muscles are interlaced with oblique muscles.

(iv) There is another layer of oblique muscles present next to the interior longitudinal muscles.

(v) Subcuticular cells are in two rows and a few of them are scattered all over its surface.

(vi) Middle longitudinal muscles are present.

(vii) Posterior sphincter muscles are in 3–4 bands.

(viii) Exterior circular muscles are present but feebly developed.

(ix) Basal circular muscles are present in bands at its base.

(x) Anterior sphincter, lateral exterior circular and middle circular muscles are absent.

(*f*) The Acetabulum:

The circular musculature of the acetabulum is not identical in the dorsal and ventral halves.

(*g*) The Excretory System:

The excretory canal is in level with the excretory vesicle.

(*h*) The Lymphatic System:

Two main lymph vessels are longitudinal and their branches surround the internal organs.

(*i*) Ratio between the length of the oral sucker and the length of the body is:—1 : 9·1–1 : 10·5 in flattened specimens and 1 : 4·2–1 : 4·6 in sagittal sections.

(*j*) Ratio between the diameter of the acetabulum and the length of the body is :—1 : 4·1 in flattened specimens and 1 :1·9–1 : 2·3 in sagittal and longitudinal sections.

(*k*) The Genital System:

(i) Cauliflower-like testes are diagonal in position.

(ii) Pars-musculosa and Pars-prostatica are very strongly developed.

(iii) The walls of the genital papilla are studded with genital sphincter papillæ.

(iv) Ventral atrium is without genital atrial-radial layers of muscles.

(v) Genital atrium is with genital atrial-radial layers of muscles.

(vi) Laurer's canal crosses the excretory vesicle.

(vii) The genital pore is situated on an elevated area.

(*l*) Size of the egg 0·104 × 0·06 mm.

MORPHOLOGY AND NATURE OF BLOOD AND MEAT SPOTS IN HEN'S EGGS*

By Ganpati Parshad Sharma, M.Sc., Ph.D. (Panjab), Ph.D. (Edinburgh),
Animal Geneticist, Government Livestock Farm, Hissar, Panjab (I).

Introduction

Although the eggs with blood and meat spots are quite edible yet the presence of even a slight trace of blood in an opened egg causes such a psychological effect on the mind of the consumers that they cannot help complaining about it to the poultry farmer. The latter, in order to please his customers, takes extra care in candling out these defective eggs and in doing so he sometimes discards even perfectly normal eggs. Since all such eggs are not marketed they constitute a considerable loss to the poultry farmer. The problem of blood and meat spots, therefore, has attracted the attention of a number of workers in recent years.

Previous Literature

Meat spots have frequently been described as pieces of glandular tissue or abnormal growths which have been torn from the wall of the oviduct during the passage of an egg through it. Benjamin and Pierce (1937) believe that these are due to an abnormal condition of the oviduct. Burmester and Card (1938), however, showed that red blood corpuscles or a significant amount of iron was present in all except 3% of the meat spots examined by them.

Evidence was presented by Nalbandov and Card (1941 and 1944) to indicate that the haemorrhages which resulted in the formation of blood clots occurred before ovulation. These blood clots were, according to them, transformed into meat spots by changes in *p*H and high environmental temperatures. The transformation took place either before ovulation, or during egg formation, or even after the egg had been laid. They attempted to prevent intra-follicular haemorrhage experimentally by the administration of vitamins A, C, D, E, K and P but were unsuccessful.

Lucas (1946) prepared smears from blood spots and demonstrated macrophages and fibroblasts in addition to intra-vascular cell types. (It was also suggested that the transfer of viable parent connective tissue cells to the egg might have some significance in the problem of transmission of lymphomatosis and other avian diseases through the egg.)

Denton (1947) observed that in general the eggs from an individual hen contained meat spots which were predominantly of one colour. The

* This work was carried out at the Institute of Animal Genetics, Edinburgh, where the author worked as Government of India Research Scholar during the period 1945–47.

transformation of a blood clot into a meat spot, according to him, was influenced only by the time which elapsed between the haemorrhage and the subsequent removal of the blood clot from the body cavity along with the egg content.

Material and Technique

All the candled out defective eggs laid by the Institute flock of Brown Leghorn birds during the period from November, 1945 to the end of February, 1947 were opened and their contents thoroughly examined. Altogether 297 such eggs formed the basis on which this study was made.

A record was kept of the gross appearance and location of all blood and meat spots encountered.

To determine the actual position of the blood spot the yolk with the blood spot on it was carefully separated from the albumen and after being agitated for a few minutes in 0·8% normal saline was immediately fixed in Formol Saline. Dehydration was done as usual by passing it through up-graded alcohols; cedarwood oil was used as a clearing agent. The yolk was then embedded *in toto* in paraffin but for histological examination only the portion with the blood spot on it was used to prepare sections.

Similarly the coloured and white meat spots were also fixed and prepared for sectioning. During the earlier part of the investigation the fixatives used were mainly Bouin's and Formol Saline, but later on Flemming—without acetic was also employed. Direct study of normal and degenerating yolk immersed in a drop of 2% osmic acid was also made.

Sections were cut 5-6μ thick and, in general, stained with Delafield's hæmatoxylin followed by alcoholic Eosin. The following stains were also used: 0·5% Iron-hæmatoxylin, Thionin blue, Mucicarmine, Mucihæmatin, Giemsa's, Mann's and Wiegert's Fibrin stain. Prussian blue and Feulgen's reactions were employed to detect the presence of iron and nuclear chromatin respectively in white meat spots.

In order to overcome the existing confusion with regard to the classification of foreign substances found in the hen's egg, all the blood formations (dots, streaks, sheets and clots, etc.) which are in close adherence to the vitelline membrane have been included under the term 'blood spot'. The term 'meat spot' has been reserved for all the discrete solid substances lying either free in the egg albumen or entangled in the chalazæ.

Observations

Morphology of Blood Spots

The blood spots vary greatly in size and shape (Plate I, Figs. 1–5). The smallest of them is no larger than a pin-prick and it is extremely difficult to identify such faults by candling. In some eggs, however, the blood spot is so large as to cover almost the whole yolk (Plate I, Fig. 1).

The blood spots are usually in the form of sheets or streaks adherent to the yolk. The sheets may be thin or thick, the latter being darker in colour than the former. Sometimes they are very faint, discontinuous streaks (Plate I, Fig. 3), but they may also be quite thick and distinct (Plate I, Fig. 2). In some cases the blood spot is in the form of a thick and rounded clot intimately attached to the yolk (Plate I, Fig. 4).

Very often it is seen that the blood spot is situated on that pole of the yolk which is towards the broad end of the egg. Occasionally associated with such a blood spot can be seen a blood streak which may be either narrow or broad (Plate I, Fig. 5). This streak may or may not end in a large blood clot but it is usually surrounded by the fibres of the chalaza. Consequently the blood streak also reveals in some cases the typical twisted appearance of a chalaza (Plate I, Fig. 5).

Figure 1 (Plate II) shows the section of a blood-spotted yolk. The spot is in the form of a sheet and can be seen lying in between the two membranes covering the yolk. Figure 2 (Plate II) reveals a portion of the same section under higher magnification. Here can be easily seen a mass of blood cells separated from the yolk by means of the vitelline membrane. The outer membrane covering the blood cells is identified as the chalaziferous layer. Most of the blood cells at this stage are apparently quite normal as their nuclei and cytoplasm take up the usual blood stains (Plate II, Figs. 3 and 4). A few of them, however, degenerate and these are represented only by their nuclei.

Morphology of Meat spots

Meat spots also show great variation in size, shape and colour. They may be found in any part of the egg albumen, lying either free or entangled in the fibres of the chalazæ (Plate I, Figs. 6–8). The smallest of them may be of such an order that it can easily be overlooked by the naked eye in an opened egg, but the largest could readily be distinguished by candling through the shell by even an inexperienced observer. They are usually rounded in shape but may be angular and sometimes elongated. The colour is generally dark red but they may be red, liver-like or of various shades of brown. Some of them are perfectly white or white with some red or brown specks included.

In Figure 5 (Plate II) a section of a red meat spot is shown. It reveals a central mass of blood cells surrounded by a fibrous layer. Figure 1 (Plate III) depicts a portion of the same section under higher magnification. Here the granular substance present in between the central mass of blood cells and the outer fibrous layer is seen infiltrating into the mass of blood cells; the blood cells are still normal except that their cytoplasm does not take up any stain. This, however, is not a general rule but depends rather upon the state of degeneration of the blood cells in particular cases. In Figure 2 (Plate III) a section of another red meat spot is shown in which some of the blood cells are quite normal but the cytoplasm of others does not stain.

With the progress of degeneration the meat spots show extensive vacuolization due to the complete disintegration of blood cells some of which are, at this stage, represented by their nuclei only (Plate III, Fig. 4). These nuclei have a tendency to group together and can be seen in the section of a white meat spot with a red speck in the centre (Plate III, Fig. 5). A piece of the white portion of this meat spot is shown under high magnification (Plate IV, Fig. 1) and reveals it to be made up of coagulated albumen in which are seen masses of degenerating yolk in addition to the blood

cells. A little albumen is invariably coagulated outside the fibrous layer surrounding the coloured meat spots and very often normal and degenerating blood cells can be seen in it (Plate III, Fig. 3). Degenerating yolk can at times be identified in the coagulated albumen and even entangled in the constituent fibres of the layer surrounding the coloured meat spot (Plate IV, Fig. 2).

Generally white meat spots have as their basis such a coagulated mass of albumen but they may show great variation with regard to the amounts of albumen, degenerating blood cells and yolk they contain. In a perfect white meat spot, however, there are few, if any, blood cells and these, if present, are in an extremely degenerate condition. The bulk of a white meat spot consists of coagulated albumen mixed with yolk in various stages of degeneration (Plate IV, Fig. 3).

It is not uncommon to observe a few cells with extreme vacuolation of the cytoplasm in a white meat spot but it becomes increasingly difficult to identify these in view of the general degeneration in progress. Even broken egg membranes are sometimes included in white meat spots. For further details regarding white meat spots please also see Sharma (1949*a*).

Discussion

Origin of Blood and Meat Spots

In general, blood spots are structurally composed of a mass of blood cells lying in between the two membranes enveloping the yolk. The inner covering is the vitelline membrane and the outer is the chalaziferous layer.

As early as 1898, M trophanow also noticed the presence of blood cells in the thickness of the envelope of yolk (enveloppe du jaune) which, according to him, consisted of two layers namely the external or the albuminous layer and the internal or the vitelline membrane. This albuminous coat of the yolk envelope may be identified as the chalaziferous layer.

It has been shown in this study that the coloured meat spots also are encapsuled by a fibrous layer which stains exactly like the chalaziferous layer. It seems highly probable, therefore, that the chalaziferous layer of the ovum and the fibrous covering of the coloured meat spots are similar structures and are secreted in the same region of the oviduct.

During the course of another investigation (Sharma, 1950) evidence has been obtained that the chalaziferous layer is secreted by the posterior half of the infundibulum to which the name 'chalaziferous region' was given by Richardson (1935). It can, therefore, be inferred that blood spots and coloured meat spots are present before the egg reaches this region of the oviduct and in consequence the lower portion of it can safely be excluded as the source of blood and coloured meat spots.

This conclusion is further supported by the fact that in most of the double yolk blood-spotted eggs the blood spot is present on one yolk only.

It was not uncommonly held that blood spots are formed as a result of haemorrhage at the time of ovulation following the rupture of a small blood vessel near the stigma. However, the observations on ovulation in timed laparotomized hens made by Nalbandov and Card (1944) have shown that bleeding may occur at this time but it is so rare and insignificant

a phenomenon that it cannot be held to be an important agency in producing blood spots in eggs. They further state that the bleeding is intra-follicular and that it may occur several days before ovulation. Though they have never observed active intra-follicular bleeding in laparotomized hens they have noted follicles containing small as well as large submembranous haemorrhages in ovaries both excised and in situ. They have also observed the yolks being released with small and large blood clots adhering to them although there was no active bleeding at the time of ovulation.

Experience derived from the present investigation confirms the findings of these workers as follicles were encountered containing submembranous haemorrhages (Plate IV, Fig. 4). How extensive intra-follicular bleeding can be was shown by an abnormal egg laid by a Brown Leghorn hen of the flock at the Institute of Animal Genetics. In this egg, instead of a normal yolk, there was a complete follicle, surrounded by the usual layers of albumen, shell membranes and shell. The follicle appeared to be filled with blood and very little yolk could be detected. (For a detailed description of this egg please see Sharma, 1949*b*.)

As already pointed out by Nalbandov and Card (1944) bleeding may occur anywhere in the follicle. If it is slight the blood remains in between the vitelline membrane and the follicle and thus forms a small blood spot on the former. However, if the bleeding is copious the whole of the vitelline membrane may be smeared with blood and the blood may even accumulate in the pedicel and its funnel-shaped base. This results in the formation of a blood streak with or without a blood clot at its tip and remains attached to the main blood spot on the vitelline membrane. Since many of the formations of this type are seen on that pole of the yolk which is towards the broad end of the egg (Plate I, Fig. 5) and most of the eggs are laid with pointed end first, the hypothesis stated above seems to be quite acceptable. This is further supported by observation on the abnormal egg, referred to above, in which the pedicel contained a blood streak within it.

Frequently during ovulation, this blood streak, with or without a clot at its tip, loses its connection with the main blood spot on the vitelline membrane and may become an inclusion in the albumen of the same egg or of subsequent ones.

When such a blood clot reaches the 'chalaziferous region' of the oviduct it is surrounded by the fibrous layer secreted there and thus forms a meat spot. If this remains lying in the oviduct then, simultaneously with the degeneration of the blood cells, the adherent albumen is also coagulated on its surface giving it a whitish appearance. In these meat spots, however, reddish specks can still be demonstrated in the centre.

According to Nalbandov and Card (1944) all meat spots, including white ones, are merely degenerated blood clots resulting from changes in *p*H of the albumen and that the transformation from red to white meat spot is hastened by high environmental temperatures. It was proved experimentally by using artificial blood clots in albumen and also in buffer solutions of known *p*H exposed to temperatures of 50°F. and 88°F.

A repetition of their experiments carried out at Edinburgh at a temperature of 103°F. did not change an artificial blood clot into a white meat

spot. Blood and meat spots from infertile eggs which had been incubated for more than 7 days were still not white. The colour of the meat spots in such eggs changed from red to dark red, brown or even tan but never to white.

Artificial and natural blood clots kept in 0·8% normal saline changed their colour to pinkish white leaving the medium reddish even at ordinary room temperature after a few days. However, on sectioning these and also the artificial and natural blood clots and coloured meat spots which had been in the incubator for more than a week the same appearance as that of the section of a white meat spot was not obtained. In all sections from the former blood cells in various stages of degeneration could always be seen.

A typical white meat spot, as far as the observations go, is formed in the oviduct by the coagulation of the albumen around free yolk left degenerating in the oviduct by the rupture of the membranes surrounding it. Pieces of the broken membranes are sometimes visible as inclusions in white meat spots. For details please see Sharma (1949*a*).

Frequently blood cells and also some other cellular elements can be detected in white meat spots but, because of the extensive degeneration, it becomes increasingly difficult to identify them. It is quite possible that these cells may be derived, either from the follicular epithelium or from the developing germ of a yolk which has ruptured in the oviduct.

Lucas (1946) has described macrophages and fibroblasts in addition to intra-vascular cell types from smears of blood spots. Though it has not been possible to confirm his findings many of the weird structures figured by him have been noted in sections of white meat spots. It is clear that the problem of white meat spots is one that requires further evidence from an experimental approach towards its solution.

The so-called 'bloody white' appears to be formed by the dissolution of a blood clot as frequent observations have shown that the albumen in the proximity of a large blood spot or a red meat spot is blood coloured. Sometimes it is even possible to detect blood cells in such albumen under the low power of a microscope. This is further substantiated by observations on artificial blood clots which dissolve out, sometimes completely, leaving the medium reddish.

It is also possible that the 'bloody white' may be produced following haemorrhages from the wall of the oviduct. Nalbandov and Card (1944), however, could not succeed in producing 'bloody white' by injecting blood in the magnum region of the oviduct.

The so-called 'cloudy white', according to Nalbandov and Card (1944), results from the bloody white after suitable *p*H changes, provided the temperature is favourable. It appears more probable, however, that the cloudy white is produced by the disintegration of the chalazæ and the dispersion of the free yolk granules.

Summary and Conclusions

1. Blood spots in eggs are due to intra-follicular bleeding. If the haemorrhage is only slight it results in the formation of thin sheets and

streaks of blood in close adherence to the vitelline membrane. Copious bleeding, on the other hand, leads to the formation of large blood clots which, if separated from the yolk, are included in the egg albumen and form coloured meat spots.

2. White meat spots are formed in the oviduct by the coagulation of albumen around a degenerated coloured meat spot, degenerating free yolk, or even broken egg membranes.

3. The so-called 'bloody white' appears to be due to the dissolution of a large blood spot or a coloured meat spot.

4. Cloudy white may be formed by the disintegration of the chalazæ and the dispersion of degenerating free yolk granules.

Acknowledgments

I wish to express my sincere thanks to Dr. A. W. Greenwood for his very kindly going through the manuscript of this paper. Thanks are also due to Mr. G. R. Knight for taking the photo-micrographs.

ON THE STORM VARIATIONS OF COSMIC RAY INTENSITY

By Om Parkash *and* H. R. Sarna, *Panjab University Physics Department, Government College, Hoshiarpur, Panjab (I).*

Abstract

A brief discussion of the magnetic storm effects on cosmic radiation is followed by the analysis of observations taken at Lahore (22° N.) during February 12–April 8 (1947), a period of pronounced solar activity. The Cosmic Ray intensity I was measured by a triple coincidence telescope and the magnetic data for the same period obtained from the nearest magnetic observatory at Alibag (Bombay). It is found that over this period of almost two months the correlation coefficient between I and H though showing a slight positive tendency, is not statistically significant. However, during fairly strong storms on February 16, and March 2, the two quantities $\Delta I/I \; \Delta H$ and $H \; \Delta I/I \; \Delta H$ are negative in the first, and positive in the second storm. The variations are discussed in the light of Chapman's and Alfven's hypotheses.

Introduction

It is well known (Hess, 1939) that regular and irregular variations of cosmic ray intensity I with time, after being corrected for temperature and pressure changes, do exist; and that some of these variations are simultaneously observed at widely separated places all over the globe. It is also observed (Forbush, 1937; Hess and Demmelmair, 1937; Duperier, 1942; Hess and Illing, 1935; Sarna and Parkash, 1949), that, generally speaking, during the time of appearance of the sun spots, earth's horizontal magnetic field H shows large fluctuations and simultaneously large changes in I are observed.

For instance, in a storm occurring on February 27–March 6 (1942) Duperier (loc. cit.) observed a 12% decrease in I and in another storm (January 29–February 12) in 1946, Duperier and McCaig observed a 10·5 $\pm$0·4% decrease. A negative correlation existed between I and H during these storms although, according to Clay and others in the case of storms on March 1, 1942, the correlation is found positive if the calculation had been restricted to this day, which from their point of view is undoubtedly the most important of this storm. Forbush (1938) and Demmelmair observed a very pronounced positive correlation (I increasing with H) between the intensity changes of cosmic rays and geo-magnetic horizontal force H during several storms in 1937-38. Forbush also reported the case of a storm occurring on August 21–25 (1937) when a decrease and a following increase of H by 120γ ($\gamma = 10^{-5}$ gauss) produced almost no change in I. There are also cases (Duperier, and McCaig, 1946; Neher

and Roesch, 1948; Dolbear and Elliot, 1947) when no appreciable change in H was observed but C.R.I. showed variations of the same order as observed in strong magnetic storms. The storms are termed 'effective' and 'non-effective' accordingly, though the cause is not clearly understood. Another important observation by Clay and Bruins (1938) at 54° latitude showed that under 110 cm. of Fe shield they did not notice any change in I. This means that harder rays ($E > 8 \times 10^9$ ev) are not affected.

The magnetic storm effects on I are quantitatively expressed as $\Delta I/I/\Delta H/H = H\Delta I/I\Delta H$, i.e. the ratio of the relative change in cosmic ray intensity and of the horizontal magnetic force. It is found (Ref. 1) that this ratio does not remain constant but varies from storm to storm.

Thus, out of this mass of diverse results, it appears that if at all, there is any relation between I and H variations, it will not be so simple. In fact T. H. Johnson (1938) has remarked that in spite of the close relationships observed between I and H the two quantities may not be casually related. However, the fact, that storm variations of cosmic ray intensity are world wide (these variations in I have been observed from 0·6° geomagnetic lat. (Huancayo) to 75° geo. lat. (Godhavan, i.e. equator to the poles)) a study of these effects at different latitudes can be helpful in giving valuable information about the energy distribution in the spectrum of cosmic radiation.

The observations of which the analysis is reported in this paper were taken with a view to find if any correlation existed between I and H at the lat. of observation, i.e. 22° N. (Lahore). These observations extend over two months period (February–April 1947) when there was pronounced solar activity and some strong magnetic storms.

Experimental Procedure and Results

A triple coincidence counter telescope (Parkash and Sarna, 1948) was employed for the present study. The cathodes of the counters were 2·5 cm. in diameter and 35 cm. long and with a distance of 25 cms. between the extreme counters, the zenith resolution was 11·3°. The telescope was set up vertically with its plane in the magnetic meridian and hourly counting rate, observed during the daytime for nearly two months, beginning from 12th February to 8th April, 1947. Hourly values of H for the same period were obtained from the nearest magnetic observatory at Alibag (Bombay). After correcting the counting rate for the temperature (temp. coeff. = −0·18%/°C.) and pressure (pressure coeff. = −6·4%cm. Hg) the daily means were calculated. The mean of the horizontal intensity H was also found for each day for the same period of the day. The results are shown in fig. 1. It is found that the correlation coefficient (r) given by

$$r = \frac{\Sigma (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\Sigma (x_i - \bar{x})^2}\sqrt{\Sigma (y_i - \bar{y})^2}}$$

(where x_i and y_i are the two variables and $\bar{x}$ and $\bar{y}$ their means) between the daily means of I and H over this period is positive. ($r = +0{\cdot}14$), showing a tendency towards parallelism between I and H although its value

is too low to be statistically significant. For the individual storms which occurred on the 16th of February and 2nd March (1947), H changed by 135 and 253 gamma respectively during a period of nearly four hours. Our observations of I in relation to H expressed as

$$\frac{\Delta I}{I \Delta H} \text{ and } \frac{H \Delta I}{I \Delta H}$$

come out to be $+ 0{\cdot}097 \pm 0{\cdot}031\%/\gamma$ and $+ 38{\cdot}3 \pm 12{\cdot}3$ in the storm occurring on 2nd March, and $-0{\cdot}103 + 0{\cdot}060\%/\gamma$ and $-39{\cdot}7 \pm 23{\cdot}0$ in the storm on February 16. (For these particular storms, the calculations were made on the basis of hourly means.) The values seem to correspond with those of other observers, though the errors in our case are somewhat larger.

Discussion

Our results for a period of two months indicate that I values at Lahore and H values at Alibag (Bombay) during magnetically less disturbed days may not be correlated, as the magnetic changes observed at one place may not be effective at another distant place. However, during strong storms, the changes are observed simultaneously all over the earth and in storms of 16th February and 2nd March we found a definite effect on I. The important thing is, that at the same place, the two storms gave opposite correlation, in one negative and in the other positive.

In order to explain these we consider the storms in general. As mentioned earlier, one finds that during a magnetic storm, any one type of change, out of the following might take place :—

(i) An increase in I with H (+ve correlation).
(ii) A decrease in I with H (−ve correlation).
(iii) Large change in I with no apparent change in H.
(iv) No change in I though H might show a large change.

Further that these changes occur and have been observed right from the equator (Huancayo 0·6°) to the pole (Godhavan 75°) and as shown by Clay and Bruins in their observations at 54° Lat., harder rays ($E > 8 \times 10^9$ ev) observed under a shield of 110 cm. Fe remained unaffected.

The above facts may be accounted for in terms of the Störmer and Lemaitre-Vallarta theories. According to these views any change in H should affect the cosmic ray intensity. At a given place the minimum energy, that can reach, is defined by the geomagnetic latitude, hence assuming a certain energy spectrum any change in H will allow or cut off a part of the spectrum thereby producing an increase or a decrease in I. Alfven (loc. cit.), however, has the view that (i) as these changes occur even at 75° Geo = Lat. where changes in H should not produce any effect on I and (ii) that changes in I as much as 20% cannot be accounted for on the above views, the above hypothesis is untenable. Not only that, the above theory demands an antiparallelism between I and H whereas people have reported definite positive correlation. Lemaitre-Vallarta theory completed with a ring-current hypothesis as given by Clay and Bruins gives a satisfactory explanation of the parallelism between I and H.

According to Alfven, the variations observed in I are caused by the electrostatic potential changes of the earth due to the approach of ion clouds from the sun. During a storm a cloud of the ions emitted from the sun, and moving in the sun's magnetic field, is polarized with the advancing side becoming negative and the following one positive and hence a potential difference $\approx 50\times10^6$ volts or even higher (10^9) volts exists between the two ends of the cloud. As the earth quickly attains the potential of the cloud, it becomes negative in the beginning and positive at the end of the storm, giving an increase followed by a decrease in cosmic ray intensity; assuming of course that cosmic rays are predominantly positive. As Alfven has shown, these clouds moving with $v \approx \cdot01$ c. the 'head' of the ion cloud would take about a day in reaching the earth, the storms should start a day after the occurrence of solar prominences and the decrease a day or two still later. This is generally the case.

Alfven's hypothesis is, however, incapable of explaining (i) Clay and Bruins observations which show no change observed in cosmic ray intensity at energies $> 8\times10^9$ volts. The electrostatic potential effect should extend over the whole of the spectrum (though with different magnitudes depending on the shape of the energy spectrum) and a change should be observed even in this region.

(ii) Our case of variations in two storms with apparently no connection between the two.

(iii) The observations of Dolbear and Elliot where an initial increase in I was observed at about 18 hours on the 25th of July and a very intense flare occurring at 17 hour the same day. Neher and Roesch have confirmed the fact that the start of cosmic ray effect and the visual part of the solar flare differ by about an hour, in this particular case.

Stormer's hypothesis of 'Ring Currents' (with which Chapman explains the positive correlation), in a modified form, can explain all the observed effects. According to this ion clouds emitted from the sun reaching the earth, set up ring currents in the equatorial plane round the earth, at a distance of a few times the earth's radius. The ring current increases the field outside it, while inside, it is decreased, and as most of the deflection of charged particles takes place outside the ring, the positive correlation between I and H is explained. This hypothesis, as it is, cannot explain all the observed facts and needs to be modified in the light of fresh results.

According to Clay and Bruins and Forbush all the effects can be explained by assuming (i) that the ring currents always exist and (ii) that their distance and strength may vary from storm to storm (2–16 times the earth's radius and 10^5–10^7 amps).

As the $-$ve ion cloud approaches the earth, the eastwardly $-$ve ion current which we suppose to be always existing is strengthened giving an increase in H inside the ring but a decrease outside. At the beginning of the storm H will, therefore, rise, which is generally so observed in storms, so also the cosmic ray intensity giving a positive correlation. However, if the ring is formed at a greater distance (within the range of course), the deflections may be appreciable inside the ring and we will observe a decrease in I with increase in H (negative correlation). The relative magnitudes of the speci-

fied quantities will depend on the strength of the ring current as well as its distance from the earth. Both these factors may vary from storm to storm giving different magnitudes of the observed effects. Sometimes large changes in I are observed without any appreciable change in H. In a particular case reported by Neher and Roesch 18% increase was observed at a Geo-mag. lat. of 40°, the actual storm started 26·5 hours afterwards. The observed increase coincided with a very prominent solar flare which took place nearly simultaneously. Alfven's reference is probably towards this increase which seems difficult to explain. Neher and Roesch (see also Forbush Gill and Vallarta, 1949) have explained this increase by assuming that under favourable circumstances, the sun might emit very high energy charged particles, and in the case reported by Neher and Roesch at 40° Lat. they must possess energies 6 B ev. Assuming the validity of such a process, the increase observed at 75° may be explained (as at such a latitude, lower energy is needed, and that might be comparatively easy to get). We are inclined to agree with Alfven that normal field fluctuations should produce no effect at so high a latitude. Both solar flares and storms have, therefore, to be considered in discussing the changes observed.

Another case in which H showed large variations though no change in I was observed is explained by Clay and Bruins. According to them, the cosmic rays need not be always affected by storms. A ring current at a distance of 15 times the radius of the earth does not influence the cosmic ray intensity but can give an appreciable variation of H. All other effects can be explained by assuming the existence of the rings between 2–4 × earth's radius.

The observations of Clay and Bruins with 110 cm. Fe shield ($E > 8 \times 10^9$ ev) are also explained in terms of ring current and Stormer Vallarta theories. According to this theory, lower end of the energy spectrum should be affected by changes in H and if this portion is cut off by shield of 110 cm. thickness, the rest of the spectrum should remain unaffected. No change should be observed under such conditions, as shown by Clay and Bruins. This, however, cannot be explained on Alfven's hypothesis, which would demand a variation throughout the energy spectrum, *though the actual magnitudes might differ in different energy regions.*

The changes observed can also be easily explained on the above ideas. However, in order to have a clear and better understanding of the subject, a co-operated programme of observing any such changes with apparatus of similar geometry at different latitudes can be of real help.

Acknowledgments

In the end the authors are grateful to Dr. Alexandar Wolsky, Chief Scientific Officer, UNESCO, for obtaining meteorological observations from Pakistan and to the Director of Colaba and Alibag Observatories, for supplying us with detailed magnetic data necessary for the calculations. They are also thankful to Prof. Clay, University of Amsterdam, for going through the paper and making suggestions.

THE TERNARY SYSTEM ANTIMONY-CADMIUM-BISMUTH

By RAM CHAND, M.Sc., Ph.D., *and* VED PARKASH, M.Sc.

(*Department of Chemistry, Panjab University, Hoshiarpur*)

The three binary systems involved in the problem are Antimony-Cadmium, Cadmium-Bismuth and Bismuth-Antimony. These systems are represented in one diagram (Fig. 1) along with the ternary system. The necessary thermal data are taken from 'Landolt—Borenstein Physikalisch—Chemische Tabellen' which contains a summary of previous work, and 'Metal Industry handbook' (1945).

SYSTEM ANTIMONY-CADMIUM

The full curve in the diagram (Fig. IA) corresponds with the condition of stable equilibrium and has been obtained only after inoculation with crystals of the compound Cd Sb. The dotted curve representing a metastable condition is realized in alloys cooled without stirring or inoculation. The stable curve has a maximum at 50 at. % antimony, with a eutectic point Cd Sb—Sb at 58·4 at. % antimony. In the absence of inoculation, however, the curve corresponding with the separation of free antimony is prolonged downwards, and when the separation of a second solid phase does take place it is not the stable compound Cd Sb that crystallizes but the metastable compound Cd_3Sb_2 which has its own solubility curve with a maximum at 40 at. % Sb and 423°C. as maximum temperature, i.e. a temperature 32°C. lower than that of the stable compound. This is in accordance with the general rule that metastable modifications melt or freeze at lower temperatures than the stable ones. To make clear the whole system let us consider an alloy containing 56 at. % antimony. If slowly cooled and inoculated it deposits crystals of Cd Sb (the stable compound) and shows a eutectic point 445°C. If cooled without inoculation, crystallization does not set in until later when antimony separates as the first phase and there is a eutectic arrest at 402°C. corresponding with the simultaneous separation of Sb and Cd_3Sb_2. On further cooling the reaction

$$Cd_3Sb_2 + Sb \rightarrow 3CdSb$$

occurs with considerable evolution of heat, and the solid alloy passes more or less completely, into the stable condition. To the left of the vertical line at 50 at. % antimony the compound Cd_3Sb_2 appears to be stable at low temperatures and occurs along with CdSb. But below 40 at. % antimony, only Cd_3Sb_2 is found along with Cd—Cd_3Sb_2 eutectic at 290°C.

SYSTEM BISMUTH-ANTIMONY

The two metals are completely miscible in both liquid as well as solid state, i.e. they form a series of solid solutions showing neither a maximum nor a minimum temperature.

System Bismuth-Cadmium

The freezing point curve has been determined by Kapp and Stoffel. The system is of a simple type in which there is a eutectic lying at 44·5 at. % or 59·8% Bismuth and 146°C. According to the investigations of Hycock and Neville the two metals do not form solid solutions and are entirely non-miscible in the solid state. But there is a difference of 20°C. in the readings of Kapp. and Stoffel. Barlow has given a summary of the previous work and has given 146°C. as eutectic temperature. G. I. Petrenko and A. S. Fedorov give 140°C. as the eutectic temperature. In view of the existing differences regarding the details of the system, it was repeated. It was found that eutectic temperature is 140°C. and not 146°C. as given by certain authors. The thermal data and diagram for this system are given in Table I and Fig. 2.

Thermal Investigation.—Antimony, Bismuth and Cadmium metals employed throughout this work were pure, almost free from foreign matter, and their freezing points agreed with the standards. The freezing points and other thermal arrests of the alloys were taken by means of a platinum-nichrome thermocouple. The free ends of the couple were attached to a sensitive mirror-galvanometer. By tracing a spot of light reflected from the galvanometer mirror on to a moving screen, the thermal arrests were obtained on direct time-temperature cooling curves. The couple wires at their brazed end were covered with a very thin layer of fireclay cement and inserted in the molten alloy. This formed a protection for the couple against the attack of metals and at the same time did not impair its sensitiveness. On account of its fragile nature the coating had to be repaired from time to time but this was not a long and tedious process. The thermocouple was standardized by means of the following fixed points: B.P. water = 99·5°C., M.P.Tin 232°C., M.P. Bismuth 268°C., M.P. Cadmium 321°C., M.P. Zinc 418°C., M.P. Antimony 630°C. The standardization was checked after analyzing six samples.

A 150 gram sample of each alloy was prepared by weighing out the requisite quantities of the metals on a sensitive balance. Powdered charcoal was used as protection against oxidation during heating and cooling of alloys. All proportions of the metals in the alloys were reckoned in weight per cent. The rate of cooling and the speed of the screen were regulated

to be the same for all alloys. It took about two hours for an alloy to cool from 630°C. to about 100°C. The results of the thermal analysis are given in Table II.

The numbering of the alloys.—In Fig. 3 the scheme of numbering of the alloys is given. The percentage of a metal in an alloy is represented on the well-known system of distances from the sides of an equilateral triangle. Starting from the apex or antimony corner the alloys are numbered from left to right on lines parallel to the Cadmium-Bismuth base. By this system it is easy to locate alloys on Fig. 4.

The liquidus surface.—In Fig. 4 the isothermals of the freezing points of the alloys are given. The solid solutions formed by Sb with Bi extend fairly deep into the whole system and this solid solution area is represented by area Sb A B C Bi. Microphotographs I, II and III are from this area. Photograph I is of a pure binary solid solution of Sb and Bi while II and III represent alloys Nos. 43 and 74 which show two phases only. The gradient of the isothermals is regular from Sb corner to Bi corner and isothermals are slightly inclined to the base of the triangle or Bi-Cd line.

Area A B C Cd is very much complicated due to the presence of two binary compounds CdSb and Cd_3Sb_2 and due to the meta-stable part of the curve representing the system Sb-Cd in which Cd_3Sb_2, which sometimes separates earlier than Cd Sb, changes into Cd Sb with evolution of much heat thus masking all the latter arrests. This part is represented on the diagram roughly by area A D E F. Microphotograph No. IV of the alloy No. 40 which lies in this area depicts very clearly the change of one phase into the other represented by the equation $Cd_3Sb_2 + Sb \rightarrow 3$ CdSb.

There is another small area G Cd.C Q in which Cd separates out. The general slope of the isothermals in this small area is from Cd corner to C. Area D E F B Q G has got a small hump near B which may be due to a ternary compound. But from the present study nothing can be said definitely as to its presence or absence. There are chances for the formation of two ternary compounds one of CdSb with Bi and the other of Cd_3Sb_2 with Bi. All over, this area has three arrests which are supported by three phases shown in microphotographs of alloys Nos. 91, 95, 96 on line 5% Sb and micro-photographs of alloys Nos. 59, 63 and 77. These three phases indicate the presence either of a ternary eutectic or a ternary compound or some other complexity. It has not been possible to locate the position of any of these two major possibilities with great definiteness and are therefore, not shown on the diagram.

Isothermals of Binary Arrests.—From the alloys lying in area Sb Bi C B F A a solid solution of Sb-Bi separates out on freezing as first solid phase. The change in composition of the liquid portion of the alloy therefore, always follows a straight line drawn from the Sb-Bi base joining the binary valley A F B C. This is made clear by graphs Nos. 5 and 6 representing section through 5% Bi and median through antimony. The section through 5% Cd Fig. 7 shows very clearly this very fact.

About the rest of the area nothing is very clear as yet. Median through Cadmium and section through 5% Antimony Figs. 9 and 8 fix clearly the position of the two binary valleys.

Ternary arrest which is obtained can most probably be due to a ternary eutectic, but examination of micro-structure of a large number of alloys in this area has so far failed to show the position of the ternary eutectic. The third arrest which is obtained in this area is 140 which coincides exactly with the freezing point of binary eutectic of Cd-Bi and can be due to this very phase, and the ternary eutectic may be entirely absent or the binary and the ternary eutectics may be very close to each other.

The two compounds Cd_3Sb_2 and CdSb are stable at temperatures up to their melting points. To clear up the whole problem it now appears

essential that systems Cd Sb-Bi and Cd_3Sb_2-Bi be studied. Also the large triangle be subdivided into three small ones and three ternary systems Cd-Bi-Cd_3Sb_2, Cd_3Sb_2-Bi-CdSb and CdSb-Bi-Sb, be studied.

Summary

Thermal analysis and microscopic study of a large number of alloys of the ternary system Antimony—Cadmium—Bismuth have been carried out. Cd forms ternary solid solutions with Sb and Bi up to a limited composition. The rest of the area of the ternary diagram is very much complicated due to the presence of two stable compounds of Sb and Cd and also due to the meta-stable part of the curve of the binary system Sb-Cd.

ABSORPTION SPECTRUM OF LEAD MOLECULE (Pb_2) IN THE VACUUM ULTRAVIOLET REGION (600–900) A.

By B. M. Anand

University Physics Department, Hoshiarpur

Abstract

The absorption spectrum of lead vapour has been studied at 900, 1000 and 1100°C. in the spectral region (600–900) A. with a one metre normal incidence vacuum grating spectrograph using Helium continuum. An intense absorption band extending between 672–676 A. occurs when the lead is heated to 900°C. and broadens as the temperature is raised. This absorption band is attributed to diatomic lead molecule and is being reported for the first time. It shows a sharp edge towards the longer wave-length side.

It is postulated that the upper state involved in this absorption band is a repulsive state of $(Pb_2)^+$ molecule dissociating into a normal neutral atom of Pb in $^3P_0$ ground state and an excited atom of Pb^+ in $^2D_{\frac{5}{2}}$ state of the electronic configuration $6s^2$ 7d.

Introduction

Lead is the last member of the spectroscopically homologous series of elements, C (6), Si (14), Ge (32), Sn (50), Pb (82), having (P^2) electrons in their valence shells, in each case resulting in the ground state ^3P of the neutral atom. The Spectrum of C_2 is well known, but very little is known about the spectra of the elementary molecules of the remaining elements of the series.

Vapour of lead is known to form diatomic molecules (Pb_2) and its band spectrum has been studied by Shawhan (1935), both in absorption and emission. A large number of band-heads lying between 4600–5200 A. were measured and the vibrational analysis was made by him. In the extreme ultraviolet region, however, no data is available for the molecular spectrum of diatomic lead.

For some time past we have been attempting to get the inner transitions of lead, extending Beutler's (1933) investigations of the so called I^b spectra of elements. In a number of our plates a continuous band in absorption appeared, extending between 671–676 A. The band is degraded towards the shorter wave-length side, and shows a sharp edge on the longer wave-length side. This band has been studied at different temperatures and we have no doubt that it is due to diatomic lead molecule in the vaporous state.

The source of continuous radiation was a pyrex glass discharge tube 100 cm. long and 2·4 cm. in diameter, with aluminium cylindrical electrodes, containing pure helium at about 5 mm. of Hg pressure. A 15000 volts luminous tube transformer, with a small condenser of about 5000 cm. capacity in parallel, was connected to the electrodes of the discharge tube through a spark gap of about 2 mm. The weak condensed discharge in Helium produced an intense continuum between 600–900 A., first discovered by Hopfield (1930).

The main absorption chamber was a transparent silica tube 70 cm. long and 1·2 cm. internal diameter. Merck's pure lead, containing less than 0·001% Ag, was contained in a side tube attached to the main absorption tube about 20 cm. from one end. Starting from the side tube 30 cm. of the main quartz tube was wound with S.W.G. 30 nichrome wire using 100 turns. In order to ensure uniform temperature the turns were wound closer near the ends of the 30 cm. length than in its remaining portion. The whole of the 30 cm. length of the tube was lagged closely with successive layers of asbestos paper about 5 mm. thick. Above this asbestos were wound another 100 turns of the same nichrome wire and was similarly lagged with asbestos paper to reduce the loss of heat by conduction. A current 1·7 Amperes through both the heaters simultaneously raised the temperature of the absorption tube to 1100°C. This, of course, is the limiting temperature up to which the nichrome heaters can be used. Proper care is taken to lower the temperature of the heated quartz tube gradually, otherwise it divitrifies when heated above 1000°C. The temperatures above 800°C. were measured by a Cambridge disappearing filament type optical pyrometer. The lower temperatures were measured by an iron-constantan thermo-couple. The side tube containing the lead was similarly wound by a double heater and lagged with asbestos. The side tube was usually kept at a temperature lower than that of the main tube and the temperature of this side tube determined the concentration of the vapour in the absorbing column. On both sides of the furnace, adjacent to the heated portion, about 10 cm. of the silica tube was kept cool by circulating water through flexible metallic tubes wrapped round the quartz tube. This absorption tube was adjusted in between the slit of a normal incidence vacuum grating spectrograph and the helium discharge tube producing the continuum. Two four stage mercury diffusion pumps were suitably arranged to maintain the circulatory differential system. Inside the spectrograph the pressure was maintained less than 0·02 mm., while on the discharge tube side it was anything between 7 to 4 mm.

A one meter speculum metal grating with a ruled area (3×5) cm.^{2} and giving a dispersion of about 17·5 A. per mm. was used.

A technique for preparing our own plates of the Schumann type has been developed. Nelson's gelatine No. I or Kodak photographic gelatine is invariably used. A fresh batch of Schumann plates is prepared a few weeks before the contemplated exposure. The plates are stored in damp-proof tins kept in a refrigerator at 10°C. In general, the plates show good

sensitivity for about a year. The sensitivity of the plates passes through a maximum after which the deterioration is more rapid. The full size of a plate is (16×3·8) cm. and covers range of spectrum up to 2500 A. For trial purposes half plates (8×3·8) cm. are exposed. For good focus extra thin glass plates, which can be curved to 1 meter curvature, are used. On one plate up to four exposures can be given. The exposure time ranged between 40 to 60 minutes.

The condition for the development of the helium continuum are fairly critical. It appears almost equally strong at 4 to 6 mm. pressure of helium, provided the mercury spectrum is subdued to the disappearing stage and the helium is pure and dry. Three pyrex glass traps, cooled by liquid air, are employed to eliminate mercury vapour from the discharge space and the spectrograph. Two activated charcoal traps, cooled to liquid air temperature are put in the circulating system to remove traces of oxygen and nitrogen. An electrically heated silica tube containing copper oxide was introduced in the system to remove hydrogen.

The plates are measured with both a Carl Leiss and a Hilger comparator, reading up to 1/100 of a mm. The following lines, which are always present are taken as reference standards.

900° C.	675·5–671·3 (4·2) A.	148040–148960 (920) cm.$^{-1}$	18·28–18·39 0·11 e.v.
1000° C.	677·7–668·1 (9·6) A.	147560–149680 2120 cm.$^{-1}$	18·22–18·47 0·25 e.v.
1100° C.	706·0–656·8 (49·2) A.	141640–152250 10610 cm.$^{-1}$	17·48–18·80 1·32 e.v.

The band shows no structure, has a sharp head towards the longer wave length side and is degraded towards the short wave length side.

A number of attempts to extend the absorption spectrum of molecular lead in the hydrogen continuum between 1600–2000 A. have not met with success.

Discussion

The correct assignment of a single band to its emitter is usually a matter of some difficulty, as often an unexpected impurity may be responsible for the observed band. In this case, however, the band has appeared a number of times with fairly good intensity, under different conditions of absorption by lead vapour, and the identity of the absorbing molecule is not much in doubt.

It is postulated that this continuous band absorption may be due to the transitions from the ground state X of neutral lead molecule to an upper state B of the ionised molecule.

The lowest state X of the normal lead molecule may be supposed to be dissociated into two normal $^3P_0$, Pb atom and an excited atom of the Pb^+ ion with the electronic energy of 81222 cm.$^{-1}$ above the ground state of Pb^+ ion $^2P_{1/2}$ ($6s^2\,6p$ configuration). Such an excited state of Pb^+ known from the work of Earls and Sawyer (1935) on First Spark Spectrum of lead as the transition $6s^2\,6p$, $^2P_{\frac{1}{2}}$—$6s^2 7d$, $^2D_{2\frac{1}{2}}$ the total energy of this excited state with respect to ground state of neutral lead atom becomes $81222+59821=141043$ cm.$^{-1}$ In this the value 59821 cm.$^{-1}$ corresponds to the ionisation potential of lead, as given in Atomic energy states, Bacher and Goudsmit (1932). The long wave-length limit of the continuous absorption observed at the highest temperature (1100°C.) comes out to be 141640 cm.$^{-1}$ This almost exact correspondence is a very favourable support to the above postulate of the upper state to be the repulsive state B of Pb^+.

Weak ionisation continua occurring below 1000 A. and at the end of Rydberg series of bands, have been observed in the case of O_2 and N_2 by

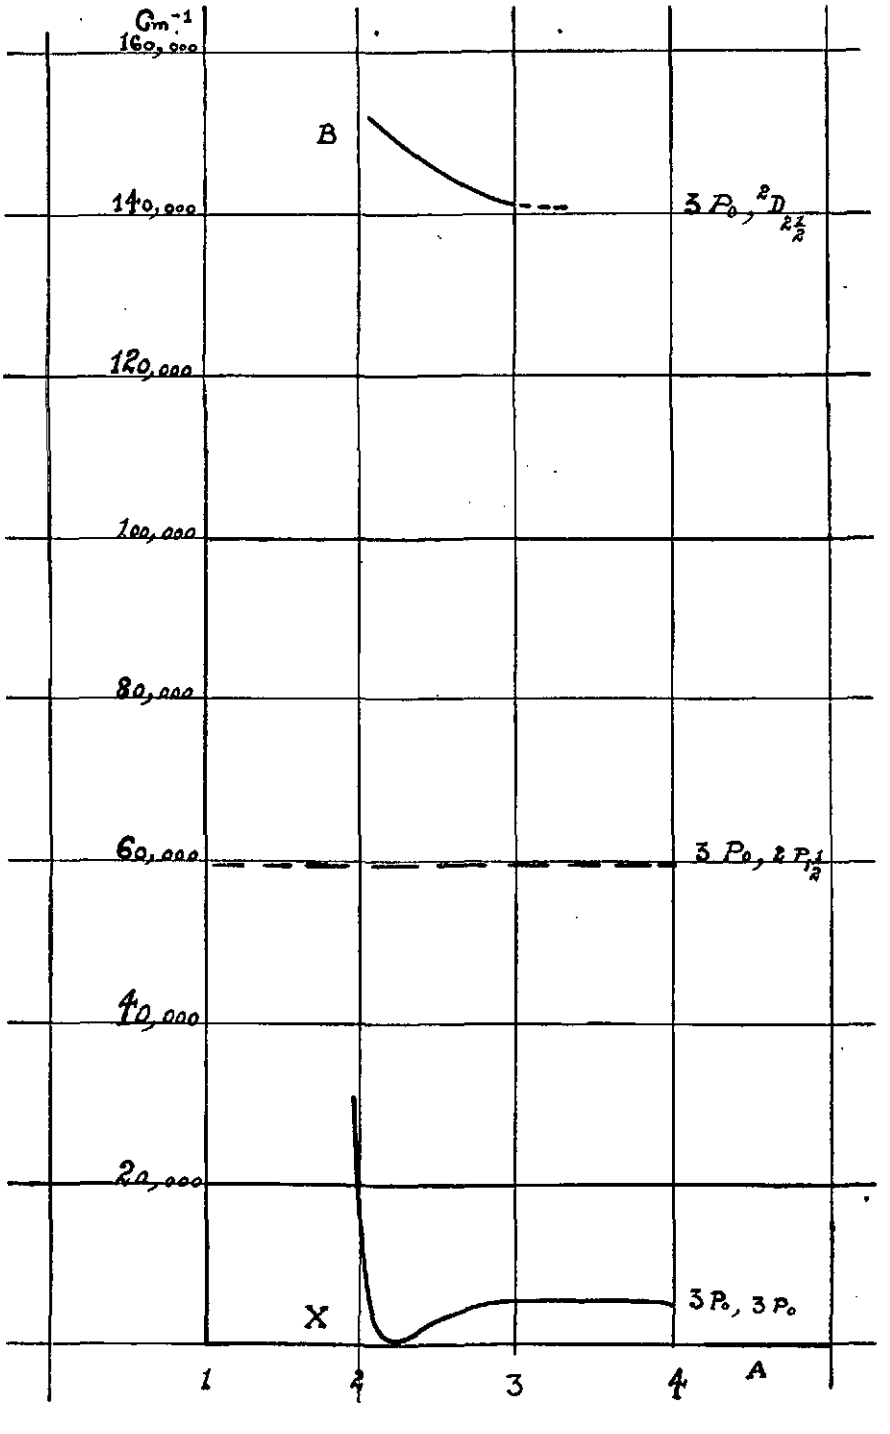

FIG. 2. Potential energy internuclear distance diagram for molecular states of Pb_2. X is the lowermost state and B is the upper repulsive state. The transitions from X to B give the continuous absorption band. The atomic states of the products of dissociation are given on the right. On the left, energy in wave-numbers is given.

Price and Collins (1935), and Worley and Jenkins (1938) respectively. From the convergence limits of the Rydberg series corresponding to the long wave-length limits of the continua, the ionisation potentials of the molecules have been calculated.

The continuous absorption of lead vapour reported in this paper is not accompanied by any discrete bands due to lead molecule. Moreover, the absorption is intense and at the highest temperature fairly extensive. These features lend support to the view that it is the case of a dissociation continuum. The long wave-length limit of the above continuum observed at the lowest temperature should give one of the ionisation potentials of the lead molecule equal to 148040/8066=18·28 volts.

If we subtract the total atomic energy of the excited ion in the product of dissociation from the above molecular energy we shall get the heat of dissociation of the molecule in the ground state.

$$E_{\text{molecule}} - E_{\text{atom}} = D$$
$$18{\cdot}28 - 17{\cdot}49 = {\cdot}79 \text{ volt.}$$

This value is also of the right order as compared to the value found by Shawhan.

Acknowledgments

The author is greatly indebted to Professor P. K. Kichlu and Professor J. B. Seth for their continued interest in this work.

POTENTIOMETRIC STUDIES IN OXIDATION-REDUCTION REACTIONS

Part XII. Oxidation with Potassium Meta-Periodate

By Balwant Singh, Appar Singh *and* Madan Gopal

Potassium meta-periodate reacts with potassium iodide in presence of sulphuric acid

$$KIO_4+7KI+4H_2SO_4 = 4K_2SO_4+4H_2O+4I_2$$

In acid medium potassium chromate, potassium permanganate, potassium dichromate, sodium iodate and potassium bromate react with potassium iodide according to the following equations:—

$$2K_2CrO_4+8H_2SO_4+6KI = 5K_2SO_4+Cr_2(SO_4)_3+8H_2O+3I_2$$
$$2KMnO_4+8H_2SO_4+10KI = 6K_2SO_4+2MnSO_4+8H_2O+5I_2$$
$$K_2Cr_2O_7+7H_2SO_4+6KI = 4K_2SO_4+Cr_2(SO_4)_3+7H_2O+3I_2$$
$$2NaIO_3+6H_2SO_4+10KI = Na_2SO_4+5K_2SO_4+6H_2O+6I_2$$
$$KBrO_3+3H_2SO_4+6KI = KBr+3K_2SO_4+3H_2O+3I_2$$

The reactions have been utilised in the quantitative determination of these substances by the potentiometric method.

Experimental

Potassium meta-periodate was prepared by the method of Bahl and Singh (*J. Ind. Chem. Soc.*, 1940, **17**, 167) by passing a brisk current of chlorine gas through a boiling solution of iodine in potassium hydroxide.

The oxidation-reduction electrode which consisted of a bright platinum foil immersed in a solution to be titrated was coupled with a saturated calomel electrode through an agar-agar potassium chloride bridge. The cell was placed in a water bath, the temperature of which was maintained at 25°C. E.M.F. of the cell was read on a potentiometer.

Potassium iodide, acidified with 7*N* sulphuric acid, was directly titrated against *M*/80 potassium meta-periodate by the potentiometric method. A known weight of each of the other substance was mixed with an excess of potassium iodide and the mixture acidified with 7*N* sulphuric acid. The excess potassium iodide was titrated potentiometrically against standard potassium meta-periodate. The titrations were conducted in an atmosphere of carbon dioxide and the mixture was kept stirred by a mechanical stirrer.

A series of potentiometric titrations were performed with different amounts of each substance. One titration for each substance, as typical of that set, is recorded in the following tables:

Discussion

In these titrations it is evident that with the addition of the titrant the E.M.F. rose steadily till the equivalence point. At the equivalence point there was a sharp jump in potential followed by a steady rise in each case.

From the volume of potassium meta-periodate used, corresponding to the equivalence point in each titration, the amount of each substance was calculated. In the following tables the values obtained are compared with the amounts of the substance taken.

The results show that potassium iodide can be determined directly and potassium chromate, potassium permanganate, potassium dichromate sodium iodate and potassium bromate determined indirectly by the potentiometric method, using potassium meta-periodate as an oxidising agent.

The authors are indebted to Dr. Vishwa Nath, Principal, Government College, Hoshiarpur, for providing facilities for the research work.

ON CIRCLES OF ANTI-SIMILITUDE

(Abstract published in the Proceedings of Indian Science Congress, 1950)

By Sahib Ram Mandan, M.A.

Certain properties of twelve circles of anti-similitude of four circles two at a time are obtained from some simple properties of a triangle by Inversion which may be enumerated as below:

(*i*) *Four sets of 6 circles in each set consisting of 3 externals and 3 internals have a common orthogonal circle.*

(*ii*) *Four sets of 6 circles in each set consisting of three internals and three externals concur.*

(*iii*) *Four sets of 6 circles in each set consisting of all externals or two externals and four internals concur.*

The centres of the circles touching the sides of a triangle $A'B'C'$ form an orthocentric tetrad of points, say $II_1I_2I_3$, $A'B'C'$ being its pedal triangle and the circle $A'B'C'$ its nine-point circle which bisects the six joins of the tetrad; the six circles on them as diameters pass through two vertices of triangle $A'B'C'$ leaving one through which the join under consideration passes; hence they are the six circles of anti-similitude for the circle $A'B'C'$ taken with one of the sides of triangle $A'B'C'$ at a time.

Consider two of them passing through $A'I$; now a circle touching the circle $A'B'C'$ and $A'B'$ and $A'C'$ must be orthogonal to them, hence A', I must be inverse points for that circle; similarly A', I_1 for another and so on for B', I_2, ... i.e., inverse of A' w.r.t. a circle touching the circle $A'B'C'$, $A'B'$ and $A'C'$ is the same as that of B' w.r.t. a circle touching circle $A'B'C'$, $B'C'$ and $B'A'$.

We may note that

(i) The circle orthogonal to any three of the six circles enumerated above has its centre at one of points of the tetrad.

(ii) Through each vertex of triangle $A'B'C'$ there pass two bisectors and four of the above circles.

(iii) Through each point of the tetrad there pass three of them.

Now let us invert the results got above w.r.t. a point O and remembering that the internal bisector of a pair of lines inverts into the external circle of anti-similitude for the inverse circles through O of the pair of given lines and the external bisector into internal circle of anti-similitude; or orthogonal circles invert into orthogonal circles; inverse points for a circle into inverse points for the inverse circle; a circle touching another circle into one touching the inverse of the second circle.

Given four circles OBC, OCA, OAB and ABC, and let O_i ($i = 1, 2, 3, 4$) be the inverses of O w.r.t. four circles touching the 3 circles through O,

then the inverses of A, B, C w.r.t. circles touching the 3 circles through each of them remain same as O_i and hence we have:

(i) Four sets of the twelve circles of anti-similitude of the four given circles two at a time have a common orthogonal circle, each set consisting of six circles, three externals and three internals.

(ii) Four sets of 6 circles in each set consisting of three internals and three externals pass through O, A, B, C: in reality these are determined by the three circles through them.

(iii) Four sets of 6 circles in each set consisting of all externals or two externals and four internals pass through O_i $(i = 1, 2, 3, 4)$.

A THEOREM ON CONFOCALS*

(Abstract published in the Proceedings of Indian Science Congress Association, 1951)

By Sahib Ram Mandan, M.A.

If the normal n *to a quadric* S *at* P *meets it again in* P′ *and another quadric* S′, *confocal with* S, *in* Q_1, Q_2, *the normals* n_1, n_2 *to* S′ *at* Q_1, Q_2, *intersect at a point* R *in the tangent plane* p′ *to* S *at* P′ *and the locus of* R, *as* S′ *varies, is a conic* († B_3, Ex. 8, p. 102) *through* P′.

Since n contains the pole of the tangent plane p to S at P w.r.t. S' the common line a of the tangent planes q_1, q_2 to S' at Q_1, Q_2 lies in p and is at right angles to n and also to n_1, n_2. Hence n_1, n_2 lie in the plane q through n perpendicular to a and intersect, say, at R. As S' varies, to each line a corresponds a point R uniquely. But the lines a envelope a conic († B_3, Ex. 2, p. 100), hence R traces a conic if we prove that it lies in p'.

Let the sections of S and S' by the plane q be the conics s and s'; let q meet the planes p, p', q_1, q_2 in lines l_p, $l_{p'}$, l_{q_1}, l_{q_2} respectively; l_{q_1}, l_{q_2} touch s' at Q_1, Q_2 and meet in R' on the tangent line l_p to s at p where q meets the line a; n_1, n_2 are normals to s' at Q_1, Q_2 and contain the poles of l_{q_1}, l_{q_2} respectively w.r.t. s, which are the poles of q_1, q_2 w.r.t. S; i.e., n_1, l_{q_1} and n_2, l_{q_2} are pairs of conjugate lines for s.

Let the pencils of lines at R and R' be related in the manner that to line l through R correspond the line l', through R', conjugate to l w.r.t. s. We notice that RP, n_1, n_2 meet their corresponding lines l_p, l_{q_1}, l_{q2} respectively in the points P, Q_1, Q_2 which lie on the line n, normal to the conic s at P and it, therefore, contains all the meets of the corresponding rays of the pencils. Now P' is a point of n, hence to $R'P'$ corresponds the line, through P', conjugate to $R'P'$ w.r.t. s, this is no other than the tangent line $l_{p'}$, at P' to s; $l_{p'}$, therefore, must pass through R, i.e. R lies on $l_{p'}$ which again lies in p'.

---

* Q. 1810, Math. Student, Vol. X, No. 2, June 1942.

† B_i stands for H. F. Baker, Principles of Geometry, Vol. i.

It is interesting to notice that RR' touches s, as it is the self-corresponding ray of the pencils.

Cor. If the normal n to a conic s at P meets it again in P' and another conic s', confocal with s, in Q_1, Q_2, the locus of the point of intersection of the normals at Q_1, Q_2 to s', as s varies, is the tangent line at P' to s. (*B_2, p. 94.)

COMMUTATIVE LAW IN FOUR DIMENSIONS SPACE S_4

(Abstract published in the Proceedings of the Conference of the Indian Math. Soc. held at Delhi in Dec. 1945)

By Sahib Ram Mandan, M.A.

1

A Set of Five Associated Lines.

Let a, b, c, d, e be a set of five associated lines (*B_4, Chap. 5) and P, B, C' be points on a, Q, A', C on b, R, A, B' on c, P', Q', R' on d, L, M, N on e such that

$A+B+C+A'+B'+C' = 0$ (syzygy determining the space);
$P+B+C' = 0 = Q+C+A' = R+A+B';$
$P'+B'+C = 0 = Q'+C'+A = R'+A'+B;$
$L+A+A' = 0 = M+B+B' = N+C+C';$ and
$A+A' = P+P'; B+B' = Q+Q'; C+C' = R+R'.$

Let $yB+zC'$, $zC+xA'$, $xA+kB'$ be points on the lines a, b, c respectively, if the plane determined by these points is to meet the line e, we must have then $l(yB+zC')+m(zC+xA')+n(xA+kB') \equiv l'L+m'M+n'N$ which is $\equiv l_1(A+A')+m_1(B+B')+n_1(C+C')$, i.e. $mx = nx = l_1$; $nk = ly = m_1$; $lz = mz = n_1$; which proves that $l = m = n$, and hence, $k = y$; i.e. the plane determined by the points $yB+zC'$, $zC+xA'$, $xA+yB'$ meets the lines a, b, c, e. Now $x(yB+zC')+y(zC+xA')+z(xA+yB')$ is a point of this plane, which may be written as $(xyB+yxA')+(yzC+zyB')+(zxA+xzC')$. If $xy = yx$, . . . i.e. if the commutative law holds, this point takes the form $xyR'+yzP'+zxQ'$ save for sign, that is a point on the line d. Hence, *the plane intersecting four lines of an associated set intersects the fifth if and only if the commutative law holds.*

2

Mutually † *Self-polar Pentads in* S_4.

Let $ABCDE$ be a pentad P_0 and A_1 a point, such that $A_1+A+B+C+D+E = 0$. The polar prime of A_1 w.r.t. P_0 contains all the ten points that have the symbols $A-B$, $B-C$, $C-D$, $D-E$, $E-A$, $B-D$, $B-E$, $C-E$, $C-A$, $D-A$. Any point B_1 in this prime may be taken as $A-B$

---

* B_i stands for H. F. Baker, Principles of Geometry, Vol. i.

† *Bull. Cal. Math. Soc.*, Vol. 33, No. 4, 1941, p. 148.

$+k(B-C)+l(C-D)+m(D-E)$, i.e. $A+(k-1)B+(l-k)C+(m-l)D-mE$, whose polar prime contains $A+(1-k)B$, $(1-k)B-(k-l)C$, $(k-l)C-(l-m)D$, $(l-m)D-mE$, $A+mE$, ... Now the condition that A_1 may lie in this prime is obtained by making a linear relation of the above points identical with A_1, i.e. $A+B+C+D+E$. Thus we should have:

(i) $A+mE+k[(l-m)D-mE]+l[(k-l)C-(l-m)D]+m[(1-k)B-(k-l)C] \equiv A+B+C+D+E$, i.e. $1=(1-k)m=(k-l)(l-m)=(l-m)(k-l)=m(1-k)$, or $(1-k)m=m(1-k)$, $(k-l)(l-m)=(l-m)(k-l)$, showing that *the commutative law must hold* and $1=(1-k)m=(k-l)(l-m)$.

(ii) $mE+A+(m-1)[A+(1-k)B]+(1-l)[(1-k)B-(k-l)C]+(1-k)[(k-l)C-(l-m)D] \equiv m[A+B+C+D+E]$, i.e. $-m=(1-k)(l-m)=(k-l)^2$ assuming the commutative law to hold here.

Now if we put $m=-r$, we have $1-k=-\frac{1}{r}$ from (i) and. then $l-m=-r^2$ from (ii) and finally $k-l=-\frac{1}{r^2}$ from (i). Putting this value of $k-l$ in (ii) we find $r=-m=(k-l)^2=\frac{1}{r^4}$, i.e. $r^5=1$ showing that r is a 5th root of unity (not unity itself) and there being four such roots we can say that there are four positions of B, only such that its polar prime passes through A_1, say B_i $(i=1, 2, 3, 4)$. Evidently polar prime of each passes through the other three completing a self-polar pentad $B_1B_2B_3B_4A_1$ w.r.t. P_0.

It is easy to note that P_0 is self-polar w.r.t. $B_1B_2B_3B_4A_1$ and they are mutually self-polar.

Hence *we establish the existence of mutually self-polar pentads if and only if the commutative law holds.*

'ON THE MORPHOLOGY OF *PARAMPHISTOMUM BATHYCOTYLE* FISCHOEDER (1901) A COMMON AMPHISTOME IN THE BILE DUCTS OF INDIAN BOVINES.'

By N. K. Gupta, M.Sc.

(*Lecturer in Zoology, Government College, Hoshiarpur*)

Introduction

Paramphistomum bathycotyle was another worm which I collected from Indian bovines in 1941 at Lahore. This worm is very common in the bile ducts of these animals. Due to their heavy infestation, they generally block the bile duct and the flow of bile is hindered.

This worm is generally confused with *P. explanatum* Creplin (1847) because the latter has got the same habitat. It is also mistaken for *P. cervi* Zeder (1790) for having antero-posteriorly placed testes.

The preliminary description of the worm was given by Fischoeder in 1901 who also recorded it for the first time. In 1923, Maplestone, on the basis of the position of testes synonymised it with *P. cervi*. Later workers, prominent amongst whom were Fukui (1929), Stunkard (1929), Sprehn (1932), Travassos (1934) and Ben Dawes (1936), concurred with Maplestone's view.

Nasmark (1937) revised the family Paramphistomidae and split up the genus Paramphistomum into many genera. He proposed the genus Gigantocotyle for *P. bathycotyle* Fischoeder (1901), *P. explanatum* Creplin (1847), *P. gigantocotyle* Brandes (1896), *Gigantocotyle symmeri* Nasmark (1937), *P. formosanum* Fukui (1929), *G. duplicitestorum* Nasmark (1937), *P. anisocotylea* Faust (1920), *P. birmiense* Railliet (1924), *P. siamense* Stiles and Goldberger (1910) and *P. fraternum* Stiles and Goldberger (1910).

Considering *P. bathycotyle*, he points out that its identity with *P. cervi* is absolutely erroneous because of differences in habitat and in the anatomical structures of the Pharynx (Oral sucker), the acetabulum and the genital atrium.

Ben Dawes (1946), in his book 'The Trematoda', has retained the genus paramphistomum and treated *P. bathycotyle* as synonym of *P. cervi*. From his book it appears that he does not recognise the scheme of classification put forth by Nasmark, 1937.

In view of the diversity of opinion about the validity of this species, its morphology is described here. My observations are based on the freshly collected material of which the whole mounts were prepared and serial sections were cut.

I have great pleasure in expressing my indebtedness to Prof. Dewan Anand Kumar, M.A. (Cantab.), Vice-Chancellor of the Panjab (I) University under whose guidance the work was carried out. I am also grateful to Dr. H. D. Srivastva, D.Sc., Helminthologist, Indian Veterinary Research

Institute, for his valuable suggestions in the preparation of this paper and to Dr. Vishwa Nath, Ph.D. (Cantab.), P.E.S. (I) for accepting it for publication in this bulletin.

Diagnosis

Shape and size: elongated, like a cone. 6–14·48 mm. in length and 4·48–4·84 mm. in maximum breadth. Cuticle: thin. Oral sucker: globular; ratio between its length and that of the body of the worm 1: 12·6–1: 12·7 in fully relaxed and 1: 9·3–1 : 10·3 in unrelaxed specimens. Acetabulum: ratio between its diameter and the length of the body 1 : 3·2–1 : 3·6 in fully relaxed and 1 : 1·8–1 : 2·1 in unrelaxed specimens. Gut: oesophagus 0·68–0·80 mm. in length. Intestinal caeca almost straight (not spiral). Reproductive systems: testes in tandem, one behind the other. Ovary somewhat spherical situated behind the posterior testis. Vitelleria on the lateral sides extending from the level of the oral sucker to the acetabulum. Laurer's canal crosses the excretory vesicle, opening dorsally behind the excretory pore. Genital pore close to the oesophagus in front of intestinal bifurcation. Eggs: 0·12×0·08 mm.

The Morphology

Paramphistomum bathycotyle is found in the bile duct of Indian bovines. Live worm is of light brown colour, reddish at the extremities. It is elongated, conical in shape, and tapering postero-anteriorly to a blunt oral extremity. Fixed specimens may be straight (Plate I, fig. 1) or slightly bent dorso-ventrally. They measure 6–14·48 mm. in length and 4·48–4·84 mm. in maximum breadth. The dorso-ventral side in unflattened specimens measures 2·64–2·8 mm. across the testicular region and 3·6 mm. across the acetabular region. The body surface is generally smooth without any wrinkle or groove. The oral aperture is situated terminally at the anterior end and the genital aperture in the anterior one third on the ventral side of the body (Plate I, fig. 1). The oral sucker is globular in shape and measures 0·64–1·12×0·6–1 mm. The ratio between its length and that of the body is 1 : 12·6–1 : 12·7 in fully relaxed and 1 : 9·3–1 : 10·3 in unrelaxed specimens. The latter specimens were cut sagittally and transversely. The acetabulum is placed at the posterior end of the body and measures 4·0–4·6 mm. in diameter in relaxed and 3·32 mm. in dorso-ventral direction in unrelaxed specimens. The acetabular aperture is either subterminal or ventral in position. It measures 0·83–1·86×2·40–2·88 mm. The ratio between the diameter of the acetabulum and the length of the body is 1 : 3·2–1 : 3·6 in flattened specimens (Plate I, fig. 2) and ratio between the dorso-ventral diameter of the acetabulum and the length of the body in unflattened specimens is 1 : 1·8–1 : 2·1 (Plate I, fig. 4). Nasmark gives 1 : 2·22 the mean ratio for the genus, and this ratio is not applicable to the fully relaxed specimens. Even in unrelaxed specimens Nasmark himself shows that this character varies from 1 : 1·50–1 : 2·60. Such a variable character should not be retained for generic diagnosis.

The cuticle of the integument is very smooth and thin (Plate II, fig. 10). It is without any striation. The subcuticular region is, however, striated.

In the oral sucker, next to the cuticle of its lumen there are bands of interior circular muscles fibres and then a wide layer of interior longitudinal muscle fibres. Oblique muscles interlacing the interior longitudinal muscles as in *P. (Cauliorchis) crassum*, are absent in this species. At about an equal distance from the cuticle and the limiting membrane, there is a row of bands of middle circular muscle fibres, the distal bands of which gradually approach the oral and aboral poles of the oral sucker. On the lateral sides, there are a few bands of anterior lateral circular and basal circular muscle fibres (Plate II, fig. 9). Just below the limiting membrane there are a few bands of exterior longitudinal muscle fibres. The radial muscles connecting the cuticle with the limiting membrane are feebly developed. The subcuticular cells are placed dorsal to the bands of middle circular muscles.

In the acetabulum (Plate II, fig. 12), underneath the cuticle there are prominent bands of circular muscles and on their dorsal side a few bands of longitudinal muscles. The bands of circular muscle fibres on the lateral sides have been counted. They are fifty-four on the dorsal exterior, forty-one on the dorsal interior, twenty-three on the ventral exterior and fifty-four on the ventral interior sides of the acetabulum. These bands were not counted by Nasmark, 1937, probably due to the badly fixed material he had at his disposal. The radial muscle fibres are present in bands alternating with the bands of the circular muscles. There are also present exterior longitudinal muscles underneath the limiting membrane and bands of oblique muscles over the lateral circular muscles.

The mouth is in the centre of the oral sucker (Plate I, figs. 2 and 3). When the specimen is left unstretched or unrelaxed the oral sucker is retracted inside with the result the body surface forms a short canal in front of it. This canal in front of the mouth also forms two papillae like projections which are due to the inward growth of the body surface (Plate I, fig. 4). The oesophagus is a tubular structure measuring 0·68–0·80 mm. in length and 0·2 mm. in thickness. Behind the genital pore, the oesophagus bifurcates into two intestinal caeca, each of which then runs along the lateral wall of the body ending blindly in front of the acetabulum. Both the intestinal caeca may be straight or might show slight curvatures during their course (Plate I, fig. 2). They are not in a spiral as in *P. (C.) crassum*. The cilia of their epithelial cells are grouped in such a way that they form villi like structures projecting into the lumen (Plate I, fig. 7).

The excretory vesicle is situated in the posterior region of the body dorsal to the testes extending backward up to the acetabular region. It is a bag like structure dilated posteriorly and tapering anteriorly to form the excretory canal which opens in the mid-dorsal line in the testicular region (Plate I, fig. 4).

In genital system, the paired testes are placed antero-posteriorly in the middle region in between the two intestinal caeca. They are slightly lobulated (Plates I, fig. 2). The anterior testis measures 2·48–3·2 × 2·40–2·80 mm. and posterior testis 2·0–2·56 × 2·40–3·08 mm. in size. A vas efferens arises from the anterior side of each testis. The vesicula seminalis is very prominent as compared to pars musculosa and pars prostatica which are shorter in size (Plate I, fig. 4). The ductus ejaculatorius unites with

the metraterm and opens into the ductus hermaphroditicus (Plate II, fig. 8).

The ovary is single and somewhat spherical lying behind the posterior testis. It measures 0·48–0·56×0·48–0·52 mm. The Laurer's canal runs on the left lateral side of the excretory vesicle and opens dorsally posterior to the excretory pore (Plate II, fig. 11). The Mehlis' gland-complex is globular in shape and measures 0·46×0·46 mm. (Plate I, fig. 7). The vitelline glands, on both sides, extend from the level of the base of the oral sucker (Plate I, figs. 5 and 6) or from the oesophagus to the acetabulum. They consist of distinct follicles overlapping one another and also the intestinal caeca at some places (Plate I, fig. 2). The two main vitelline ducts, one from each vitellaria open in the yolk reservoir (Plate II, fig. 11) which in its turn opens by a short duct into the ootype. The uterus emerges from the lateral side of the Mehlis' gland-complex and proceeds anteriorly along the left border of the posterior testis then changes its course and becomes dorsal to the anterior testis. Further it runs beneath the vas deferens and finally opens through a metraterm into the small and delicate chamber, the ductus hermaphroditicus (Plate I, fig. 4 and Plate II, fig. 8). It has a wide lumen containing a large number of eggs. The ductus hermaphroditicus opens out on the genital papilla which is strengthened by small sphincter muscle fibres. The eggs measure 0·12×0·08 mm. in size.

Name of the organ.	Measurements as given by Nasmark, 1937.	Measurements according to writer's observations.
Length of the worm ..	10·8 mm. (11–15 mm.)	6–14·48 mm.
Breadth	More than 2/5 of the length of the body.	4·48–4·84 mm.
Dorso-ventral dimension.	4·32 mm.	2·64–2·8 mm. across the posterior testicular region and 3·6 mm. across the acetabular region.
Ratio between the length of the oral sucker and the length of the body.	1 : 10·0 (1 : 12·2–1 : 15·0).	1 : 12·6–1 : 12·7 in fully relaxed and 1 : 9·3–1 : 10·3 in unrelaxed specimens.
Diameter of the acetabulum.	4·64 mm. (4·4–6 mm.).	4·0–4·6 mm. in relaxed and 3·32 mm. in dorso-ventral direction in unrelaxed specimens.
Ratio between the diameter of the acetabulum and the length of the body.	1 : 2·32 (1 : 2·5).	1 : 3·2–1 : 3·6 in flattened specimens 1 : 1·8–1 : 2·1 in unflattened specimens.
Oesophagus ..	1·0 mm. (1·0–1·05 mm.) in length.	0·68–0·80 mm. in length 0·2 mm. in thickness.
Testes	2·0 mm. (1·0–1·3 mm.) in length. 1·5 mm. (1·5–1·8 mm.) D.V. Direction.	Anterior testis 2·48–3·2×2·40–2·80 mm. Posterior testis 2·0–2·56×2·40×3·08 mm.
Egg	0·14×0·078 mm.	0·12×0·08 mm.

Remarks

From the morphology, it is quite evident that *P. bathycotyle* is not a synonym of *P. cervi* Zeder (1790) but a valid species.

With regard to the acceptance of the new genus as proposed by Nasmark, 1937, there are certain objections. His system of classification,

if adopted, will not prove practicable. In an immature specimen the units of muscles on the basis of which the various types of acetabula have been made, may not be fully developed. Moreover, the shape of acetabulum may vary with fixation.

Similarly the ratio between the diameter of the acetabulum and the length of the body depends upon the state in which the worm has been fixed. In a contracted specimen the ratio will decrease, while in a relaxed specimen, it will increase.

In my flattened specimens, the ratio between the dia. of act. and the length of body is 1 : 3·2–1 : 3·6; whereas according to Nasmark, the mean ratio for the genus is 1 : 2·22. This means that this ratio is not applicable to the whole mounts. I, therefore, prefer to retain this species under the genus Paramphistomum.

SPERM FORMATION IN CERTAIN COLEOPTERA WITH PARTICULAR REFERENCE TO CHROMOSOME NUMBERS, ACROSOME AND MITOCHONDRIAL NEBENKERN

By VISHWA NATH, SUKHDEV RAJ BAWA, RAJKRISHAN BHARDWAJ *and* MANOHAR LAL GUPTA

(Department of Zoology, East Panjab University, Govt. College, Hoshiarpur)

CONTENTS

1. INTRODUCTION

A glance at the next section of this communication, 'Previous Literature on Insect Spermatogenesis', will show that most of the previous work on insect spermatogenesis—at any rate, work carried out with the modern technique of studying the Golgi apparatus and the mitochondria—has been carried out on the Lepidoptera and Hemiptera. Bowen (1924), in his remarkable paper on 'the Formation of Sperm in Coleoptera and Aptera', states that the testicular material of *Chelymorpha* is unsuitable both for the study of the condensation of the mitochondrial nebenkern and for the development of the acrosome from the Golgi apparatus.

In view of the above, work in this laboratory on the testicular material of *Plocaederus obesus*, *Coccinella septumpunctata* and *Aulocophora foveicollis* —all coleoptera—was started by Bawa, Bhardwaj and Gupta respectively at the suggestion and under the supervision of the Head of the Department in October, 1949. The investigations were completed early this year and it has been considered best to record the findings of all the three authors in one communication, which has been prepared for the press by the Head of the Department.

Amongst the three beetles studied the testicular material of *Aulocophora foveicollis* turned out to be the most suitable inasmuch as the sperm-forming cells of this beetle are large, and the behaviour of the mitochondria and

Golgi elements can be followed easily throughout the process of spermatogenesis.

2. Previous Literature on Insect Spermatogenesis

To the best of our knowledge Gatenby (1917) was the first worker to study insect spermatogenesis with modern technique, which brings out the Golgi elements and the mitochondria clearly. Prior to this publication all the investigators on insect spermatogenesis used fixatives containing fat solvents and were thus unable to study the mitochondria and the Golgi elements correctly. Indeed, their investigations were confined mostly to the study of the nucleus.

Gatenby (1917) working on *Smerinthus* (Lepidoptera) shows that the acrosome is formed by the Golgi elements, and he also gives details of the formation and ultimate fate of the mitochondrial nebenkern. Although some of the conclusions of Gatenby were challenged subsequently by Bowen, Gatenby's publication must be considered as a pioneer one in this field inasmuch as it stimulated interest in the study of not only insect spermatogenesis but also spermatogenesis in general.

Subsequently Doncaster and Cannon (1920) published a paper on the Sperm of two species of Louse, viz., *Pediculus corporis* and *Pediculus capitis*. This work was continued by Cannon who confirmed the earlier findings in a subsequent paper on the Sperm of Louse published in 1922.

Bowen (1920, 1922*a*, 1922*b* and 1924) published four important papers on insect spermatogenesis covering the *Hemiptera*, *Lepidoptera*, *Coleoptera* and *Aptera*. In his paper on Lepidoptera Bowen (1922*b*) gave an altogether different interpretation of the detailed structure of the mitochondrial nebenkern from the earliest description of Gatenby (1917). Briefly speaking, whereas Gatenby had described a 'spireme' structure in the mitochondrial nebenkern, Bowen advanced the conception of a 'plate-work' structure. Similarly Bowen differed from Gatenby in the interpretation of the detailed formation of the acrosome.

Nath (1925), on an invitation from Prof. Gatenby, was permitted to examine the slides of Lepidopterous testes, which the latter had recently prepared, and confirmed Bowen's conclusions about the 'plate-work' structure of the mitochondrial nebenkern.

Chang-Chun Wu (1946) studied the spermatogenesis of an Orthopterous form *Diestrammena*; and confirmed the earlier conclusions of Bowen.

3. Observations

In this section will be given a comparative account of all the three coleopteran species, so as to avoid unnecessary repetition.

Spermatogonia

Of all the three coleopteran species studied *Aulocophora foveicollis* forms the most favourable material for cytological studies inasmuch as the sperm-forming cells from the spermatogonia to the ripe sperm are comparatively much larger than in either of the other two species, *Plocaederus obesus* and *Coccinella septumpunctata*. In Pl. I, Figs. 1 and 2, are shown

two spermatogonia of *A. foveicollis*. In figure 1 there is a juxtanuclear mass consisting of fine granules, which stain darkly with haematoxylin. Although most of the granules of this juxtanuclear mass are mitochondrial in nature, it is likely that a few granules are Golgi in nature, but the latter cannot be distinguished as such from the mitochondria on account of overcrowding. But this juxtanuclear mass has become almost circumnuclear in figure 2, when the Golgi material appears as a prominent juxtanuclear body of irregular form, staining more intensely with haematoxylin than the mitochondria. This Golgi mass is undoubtedly formed by the running together of closely situated Golgi granules, which could not be distinguished as such in the stage represented by Fig. 1. The nucleus of the spermatogonium reveals a prominent darkly staining nucleolus, round in form.

In Pl. III, Fig. 62, is shown the spermatogonium of *Coccinella septumpunctata*. Here the Golgi elements are not aggregated together in a juxtanuclear mass, but are spread out amongst the mitochondrial granules. One or two of the Golgi elements appear in the form of crescents.

The spermatogonia of *Plocaederus obesus* are the smallest of the three species, and reveal at best mitochondrial granules only. It has not been found possible to observe at this stage any granules, which could be identified as Golgi elements in this species (Pl. IV, Figs. 105 and 106).

Primary Spermatocytes

In the primary spermatocytes of *Aulocophora foveicollis* (Pl. I, Figs. 3 and 4) both the mitochondria and the Golgi elements are in the form of granules, the latter staining more deeply, and both are distributed uniformly throughout the cytoplasm. The Golgi elements remain granular throughout meiosis I, but they grow in size towards the later stages of this phase. On the other hand, radical changes of a chemical nature seem to have taken place in the mitochondrial material. Soon after the stage shown in Fig. 4, Pl. I, the mitochondrial granules run together and arrange themselves in the form of a horseshoe-shaped nebulous mass, which hardly reveals any definite structure within itself (Pl. I, Figs. 5 and 6). In Fig. 8, Pl. I, the mitochondria have appeared in the form of delicate bubbles, which generally put in an appearance as late as the early stages of insect spermateleosis. In other words, the running together of mitochondrial bodies to form a nebenkern in sperm formation is, in this species, *A. foveicollis*, anticipated as early as the spermatocyte stage. During meiosis I, the mitochondrial mass is roughly divided into two; and the Golgi granules which have grown in size by this time, are also sorted out roughly in two halves (Pl. I, Fig. 12).

Although the number of diploid chromosomes in *A. foveicollis* seems to be 30, the chromosomes are large and easy to count. In Fig. 10, Pl. I, thirty diploid chromosomes can easily be counted. In Fig. 9, Pl. I, which gives a polar view of metaphase I, 15 pairs of chromosomes can also be easily counted.

In the resting primary spermatocytes of *Plocaederus obesus* the Golgi elements appear in the form of crescents and granules, and the mitochondria in the form of small granules or vesicles (Pl. IV, Figs. 107–110). The

diploid number of chromosomes in this species seems to be 10 (Pl. V, Fig. 111); and the Golgi elements and the mitochondria are sorted out into two sub-equal halves as illustrated by Figs. 111 and 112, Pl. V.

In the primary spermatocytes of *Coccinella septumpunctata* the Golgi elements and the mitochondria appear in the form of crescents and granules respectively (Pl. III, Fig. 63). The diploid number of chromosomes is here also 10, as is shown by Figs. 65–71, Pl. III. It will be noted that the chromosomes of this species are much larger than the chromosomes of *Plocaederus obesus*, although the diploid number of chromosomes in both is 10.

Secondary Spermatocytes

We now turn to a description of the secondary spermatocytes and meiosis II. In all the three coleopteran species described here there is a distinct pause between the two meiotic phases. In Fig. 13, Pl. I, is shown a resting secondary spermatocyte of *A. foveicollis*; in Fig. 14, Pl. I, metaphase II; and in Figs. 15 and 16, Pl. I, telophase II.

In Figs. 113–116, Pl. V, are shown resting secondary spermatocytes of *Plocaederus obesus*; in Fig. 117 metaphase II; and in Figs. 118 and 119 telophase II. The Golgi elements in the secondary spermatocytes and in meioses II are crescent-like; and the mitochondria, which have now grown in size, are in the form of vesicles.

In Fig. 72, Pl. III, is shown the resting secondary spermatocyte of *Coccinella septumpunctata*; and in Figs. 73 and 74, Pl. III, telophase II.

Spermateleosis

As the details of the process of spermateleosis, occurring in the three species under discussion here, vary, particularly the details of the formation of the acrosome, it will be best to describe this process separately for each of the three species.

Undoubtedly the most favourable of the three species for the study of spermateleosis is *Aulocophora foveicollis*, as, apart from the fact that the cells are large in this species, the details of acrosome formation are easier to follow than in either of the two other species. A study of Figs. 19 and 20, Pl. I, and Figs. 21 and 22, Pl. II, will show that in the early spermatids the mitochondrial nebenkern is an amorphous mass, showing no structure inside its interior, the Golgi elements in these early stages existing in the form of granules varying in size. Most probably, however, the mitochondria exist at this stage in the form of extremely fine and delicate bubbles—more delicate than those figured in the resting secondary spermatocyte (Pl. I, Fig. 13). But the technique used has failed to bring out the real structure of the mitochondria, which is alveolar.

From now onward a partial breakdown and confluence of the mitochondrial bubbles take place, as is usual in insect spermatogenesis. This process results in the formation of a body, which in reality has a 'plate-work' structure (Bowen, 1922*b*), but was erroneously described as a 'spireme' (Gatenby, 1917). For the study of the beginning of this process reference

may be made to Pl. I, Figs. 17 and 18. Soon, however, the mitochondrial nebenkern assumes a spherical form with lightly staining alveoli on the periphery and more heavily staining alveoli in the centre (Pl. II, Fig. 25). The process of coalescence of mitochondrial bubbles continues, till we get a compact sphere having a darkly staining central part, from which radiate outwards a number of septa through a chromophobic peripheral substance (Pl. II, Figs. 26 and 27). Gradually the septa piercing the chromophobic part break down till they all disappear. The mitochondrial nebenkern now consists of a perfectly round central chromophilic sphere and a peripheral chromophobic part. At the same time the axial filament has put in its appearance, and piercing the mitochondrial nebenkern, it divides it into right and left halves (Pl. II, Fig. 28). During the later stages of sperm-formation the mitochondrial nebenkern undergoes a progressive process of lengthening. Side by side with this attenuation of the mitochondrial nebenkern the peripheral chromophobic material is correspondingly reduced, till it completely disappears (Pl. II, Figs. 29–32). With the lengthening of the tail of the sperm the mitochondrial nebenkern also begins to lengthen out (Pl. II, Figs. 35 and 37, and 38–47). It may be noted here that the central substance of Bowen (1922*b*) or 'Sheath substance' of Nath (1925) is conspicuous by its absence in *Aulocophora foveicollis*. But the bleb-like swellings on the tail of the sperm as described by Bowen (1922) in insect spermatogenesis are commonly met with in this species (Pl. III, Figs. 52-53).

While it is often easy to observe the minute centriole lodged in the neck region of the ripe or nearly ripe sperm immediately behind the nucleus, it is not possible to demonstrate axial filament during last stages of spermateleosis of *A. foveicollis*.

As has already been noted in the beginning of this section, it is easier to follow the details of the acrosome formation in *A. foveicollis* than in either of the other two species. The Golgi elements in the earlier spermatids of *A. foveicollis* can be easily made out as deeply staining granules of varying sizes (Pl. I, Figs. 19 and 20 ; Pl. II, Fig. 21). Soon, however, a few Golgi granules seem to come together as illustrated in Fig. 22, Pl. II. It seems likely that these Golgi granules ultimately unite to form a single large vesicle with a chromophilic rim and a chromophobic interior, which, in conformity with the terminology used by Bowen and Gatenby, may be called the acroblast. Soon, however, the acroblast loses the staining capacity of its chromophilic periphery, the whole sphere appearing as a pale structure in the finished preparations, never taking up any stain. This is clearly illustrated by Figs. 23, 24, 26 and 27, Pl. II. It must be clearly noted that only a few Golgi elements fuse together to form the acroblast, whereas the rest of them, along with the acroblast after it has secreted the acrosomal granule, are sloughed off.

The pale sphere, which we have named as the acroblast, seems to go round the nucleus till it has completed a movement through an angle of 180°. This will be made clear from a reference to Figs. 32–35, Pl. II. The meaning of this journey on the part of the acroblast, before it begins to secrete the acrosomal granule, is not clear. A similar journey on the part of acroblast has been described by Bowen in Coleoptera (1924).

Suddenly a deeply staining granule, the acrosomal granule, appears on the border of the pale acroblast (Pl. II, Figs. 38–41). It is difficult to escape the impression that the acrosomal granule is secreted by the acroblast. Soon, however, the acroblast and the acrosomal granule part company, the former shifting backward into the tail to be sloughed off subsequently, and the acrosomal granule beginning to move in front of the nucleus, where it forms the acrosome (Pl. II, Figs. 42–44).

The acrosomal granule, having seated itself in front of the sperm nucleus, applies itself to the anterior aspect of the nucleus and undergoes a process of progressive lengthening out, till it assumes the form of a needle broad at its base and narrow towards the anterior end of the sperm (Pl. III, Figs. 49–51 and 54–61).

As we have already pointed out only a few Golgi elements fuse together to form the acroblast. The remaining Golgi elements are sloughed off along with the 'acroblast' (Pl. II, Figs. 37, 41 and 45–47).

The centrosomal granule, which can be seen often in both meiotic stages, is lost to view in the early stages of sperm formation. It reappears as a definite granule in the last stages of spermateleosis at the base of the nucleus of the sperm (Pl. III, Figs. 54–61). But sometimes in favourable preparations the centriole can be seen as a distinct granule, from which the axial filament springs up (Pl. II, Fig. 31).

In the early stages of spermateleosis in *A. foveicollis* the nucleus reveals a structure which is characteristic of this phase of sperm formation in general. That is, it has a lightly staining central area and a more darkly staining periphery (Pl. I, Figs. 19 and 20; Pl. II, Figs. 21–28 and 32–35). Again, as is usually the case, there takes place a reversal of these two areas of varying staining capacity. That is, the peripheral part of the sperm nucleus now becomes lightly staining, the central part taking a deep stain. In Pl. II, Fig. 36, a beginning of this process of reversal has started and in Pl. II, Fig. 37, the process of reversal has been completed. Soon the central more deeply staining area extends right up to the nuclear membrane. The rest of the process of the maturation of the nucleus consists, as usual, of a process of condensation, till a long, compact and homogeneously staining nucleus has been formed.

In *Coccinella septumpunctata* the details of the formation of mitochondrial nebenkern closely follow those of *A. foveicollis*. But in *Plocaederus obesus* the central chromophilic part of the nebenkern progressively disappears, and the tail sheath is formed from a new substance, the 'central substance' of Bowen (1922*b*) and 'Sheath substance' of Nath (1925). The central substance puts in its appearance in the form of lightly staining granules in the chromophobic area before the final disappearance of the central chromophilic part of the nebenkern (Pl. V, Figs. 131–140).

In *Coccinella septumpunctata* a very prominent acroblast broad at one end and narrow towards the other is formed in the early stages of sperm formation (Pl. III, Fig. 79 and Pl. IV, Figs. 80 and 84). The acroblast, more often than not, stains deeply with haematoxylin. It will be recalled that the acroblast of *Aulocophora foveicollis* is perfectly spherical, whereas, in *Coccinella septumpunctata*, it is an elongated structure broad at one end

and narrow at the other. Sooner or later there appears a vesicle in the immediate vicinity of the acroblast (Pl. IV, Figs. 82, 83, 85, 87–91). This may be called the acrosomal vesicle. Soon a sharply staining granule, the acrosomal granule, puts in its appearance in the interior of the acrosomal vesicle (Pl. IV, Figs. 92–94). The acrosomal vesicle seems to condense and at the same time the acrosomal granule begins to grow in size, the result being that the acrosomal granule completely fills up the space within the acrosomal vesicle. In other words, the acrosomal vesicle as such completely disappears and the acrosomal granule, now grown in size, becomes the definitive acrosome (Pl. IV, Figs. 95–97). The acroblast and the acrosome now part company, and the acroblast begins to travel backwards as is clear from a reference to Figs. 96 and 97, Pl. IV. As it is travelling backwards into the tail the acroblast undergoes shrinkage in size and ultimately degenerates (Pl. IV, Figs. 98 and 99). On the other hand, the acrosome grows in size and begins to travel forwards in front of the nucleus (Pl. IV, Figs. 101 and 102). Seated on the anterior aspect of the nucleus, the acrosome develops into a triangular structure with a broad posterior and a fine needle-like anterior end (Pl. IV, Figs. 103 and 104).

Of all the three coleopteran species under discussion *Plocaederus obesus* seems to have the smallest sperm-forming cells. Whereas the details of the formation of mitochondrial nebenkern and its ultimate fate can be more easily followed in *Plocaederus obesus*, the details of acrosome formation are most difficult to follow in this species, as can be seen from a study of Figs. 122–129, Pl. V. The Golgi elements in the early stages of spermateleosis exist in the form of crescents, each enclosing a chromophobic area. But suddenly the crescent-shaped Golgi elements disappear from view and the only representative of the Golgi material in the cell at this stage is a small acrosomal vesicle, enclosing an acrosomal granule within it (Pl. V, Figs. 130 and 131). The acrosomal granule seems to grow in size and fill up completely the space within the acrosomal vesicle, thus forming the acrosome (Pl. V, Fig. 132). The acrosomal granule now shifts to the anterior aspect of the nucleus and there it grows into a pointed acrosome (Pl. V, Figs. 134, 138–143).

Finally with regard to the changes in the nucleus we note a sharp contrast between *Aulocophora foveicollis* on the one hand and *Plocaederus obesus* and *Coccinella septumpunctata* on the other. Whereas a conspicuous process of reversal of the chromophobic and chromophilic area of the nucleus of the maturing sperm takes place in *A. foveicollis*, in the other two species this process of reversal is conspicuous by its absence. On the contrary in both *C. septumpunctata* and *P. obesus* a sharply staining granule puts in its appearance in the nucleus at an early stage in spermateleosis, to disappear only during the late stages. The significance of this granule is not known.

4. Discussion

A careful study of Bowen's paper on the formation of sperm in Coleoptera and Aptera (1924) leaves the impression that the coleopteran sperm is most unsuitable for the study of the development of the acrosome. Indeed, Bowen says that in the Coleoptera, 'the development of the

acrosome proper is very difficult to follow, owing to its extremely small size'. We are in a position to support this statement so far as the sperm of *Plocaederus obesus* is concerned. In this species there are prominent Golgi elements in the spermatids before the spermatid has begun to elongate. But just before the process of elongation begins there appears a small vesicle with a tiny granule within it, which we have called an acrosomal vesicle and the acrosomal granule respectively. We have no evidence to show that the acrosomal vesicle with its contained granule has been actually derived from the Golgi elements, except on the basis of analogy. The acrosomal granule seems to grow in size and fill up the whole space within the acrosomal vesicle, thus forming the acrosome, which gets itself seated on the anterior aspect of the nucleus. The material, however, is much more favourable for the study of the details of the acrosome formation in *Aulocophora foveicollis* and *Coccinella septumpunctata*, in spite of the fact that in both these species of beetles we have been unable to demonstrate the origin of the acroblast from the Golgi elements; nevertheless the acroblast is a comparatively large structure in both these species, being larger in *Coccinella septumpunctata* than in *Aulocophora foveicollis*.

In *A. foveicollis* the form of the acroblast is perfectly spherical, and the acrosomal granule always puts in its appearance in its close neighbourhood, perhaps pointing towards the conclusion that the acrosomal granule is a secretory product of the acroblast. The acrosome is derived directly from this granule, after it has shifted to the anterior aspect of the sperm nucleus, whereas the acroblast shifts backwards into the tail and disappears.

In *Coccinella septumpunctata*, the acroblast is a much bigger structure: it is elongated in form with one end broad and the other narrower. It stains homogeneously with haematoxylin and never reveals any internal structure. This form of the acroblast in *C. septumpunctata* is in sharp contrast with the perfectly vesicular form in *A. foveicollis*. Suddenly a vacuole, which we have called the acrosomal vesicle, appears in the substance of the acroblast towards one end. Strange as it would appear this end is invariably the broad end of the acroblast, but for a long time the acrosomal vesicle remains closely attached to the acroblast. The staining capacity of the acrosomal vesicle increases and a deeply staining granule soon appears within its interior. This is the acrosomal granule, which grows in size. At the same time the acrosomal vesicle seems to shrink in size, the acrosomal granule thus filling up the whole space in the vesicle. The enlarged acrosomal granule migrates to the anterior aspect of the nucleus, where it forms the acrosome. The elongated acroblast shifts backward into the tail, where it begins to degenerate and ultimately is sloughed off. In *C. septumpunctata* also, as in *A. foveicollis*, it is difficult to escape the conclusion that the acrosome is secreted by the acroblast.

Bowen (1924) has described 'spermatid remnant' in the spermatid of Hemiptera, Coleoptera and Aptera. He has also described a chromatoid body in Coleoptera and Aptera, and a 'juxta-nuclear body' in the beetle *Chelymorpha*. Bowen seems to be doubtful about the homologies of these three bodies. We have not observed any of these bodies in the three species of beetles under discussion in this paper. We venture to suggest

that these bodies all belong to the category of Golgi apparatus. Nath (1944) made out a case in favour of the view that the essential structure of a Golgi element is granular or vesicular—a view which has been fully confirmed by Baker (1949). Therefore, it seems to us that the 'spermatid-remnant', 'chromatoid body' and the 'juxta-nuclear body' of Bowen are all essentially of the nature of Golgi granules or vesicles.

Bowen, who has described the details of the formation of the mitochondrial nebenkern in several species of insects, has directed attention to the development of the 'central substance' in the chromophobic part of the nebenkern in many species, particularly in the Lepidoptera (1922*b*). This 'central substance' usually forms the sheath of the axial filament. For that reason Nath (1925) calls this substance the 'sheath substance'.

It will be recalled that we have described a central substance in *Plocaederus obesus*, whereas in *Aulocophora foveicollis* and *Coccinella septumpunctata* it is completely absent.

Lastly, here we might make reference to some details of the condensation process of the sperm nucleus. It will be recalled that in *A. foveicollis* the nucleus of the early spermatids has a chromophilic periphery and a more lightly staining interior. These deeply staining and lightly staining areas are subsequently reversed, the densely staining area becoming internal. In *C. septumpunctata* and *P. obesus*, however, this process is absent. On the contrary, in both the species, the spermatid nucleus contains a deeply staining round granule, which Bowen (1924) refers to as the 'intra-nuclear body' in the beetle '*Chelymorpha*'. As in *Chelymorpha*, the intra-nuclear body ultimately disappears in both the species mentioned above.

C.S.—Central substance.
S.f.—Spindle fibres.

7. Explanation of the Plates

Figures 1 to 61 have been drawn at the stage level with Spencer 6× eyepiece using an oil immersion objective. They are subsequently enlarged two times, thus giving a total magnification of 1,200. All the figures are selected from sectioned material fixed in Flemming without acetic acid and stained with 0·5% iron haematoxylin.

Figures 62 to 104 have been drawn at the stage level with Spencer 10× eyepiece using an oil immersion objective. They are subsequently enlarged giving a total magnification of 1,900 times. All figures except 66, 69 to 71 are from material fixed in Flemming without acetic acid. Figures 66, 69 to 71 are from material fixed in Bouin's fluid.

Figures 105 to 143 have been drawn at the stage level with Leitz 8× eyepiece using an oil immersion objective. They are subsequently enlarged giving a total magnification of 400 times. All figures have been selected from sectioned material fixed in Flemming without acetic acid followed by 0·5% iron haematoxylin.

POTASSIUM META-PERIODATE AS VOLUMETRIC REAGENT

PART II—INDIRECT DETERMINATIONS

By BALWANT SINGH *and* APPAR SINGH

Government College, Hoshiarpur

In the present investigation, the authors have made an attempt to determine indirectly copper sulphate, hydrogen peroxide, dioxides of lead and manganese, formates, sodium sulphide and potassium iodide in iodine solution by a volumetric method, using potassium meta-periodate as an oxidizing agent.

Potassium meta-periodate was prepared by the method of Bahl and Singh (*J. Ind. Chem. Soc.*, 1940, 17: 167) by passing a brisk current of chlorine gas through a boiling solution of iodine in potassium hydroxide. It was filtered, washed and recrystallized from hot water.

In all titrations with potassium meta-periodate, 5 c.c. of chloroform and enough of hydrochloric acid, to keep its normality between $4N$ to $7N$ were added to titrant in a conical flask. Potassium meta-periodate was added from a burette until the titrant, which at first was strongly coloured with iodine, became pale brown. The conical flask was then stoppered and vigorously shaken, and the chloroform layer acquired purple colour due to iodine. Continued to add small volumes of the meta-periodate solution, shaking vigorously after each addition, until the chloroform layer was faintly violet. Potassium meta-periodate was then added drop-wise, with shaking after the addition of each drop, until the chloroform layer changed its colour from violet to pale yellow, due to formation of iodine monochloride. The end point was very sharp.

(1) DETERMINATION OF COPPER SULPHATE

Dissolved a known weight of copper sulphate in water and saturated the solution with sulphur dioxide. Boiled the solution and added excess of ten per cent ammonium thiocyanate slowly with constant stirring to precipitate cuprous thiocyanate. Allowed the precipitate to settle, filtered and washed with one per cent ammonium sulphate solution till the filtrate was free from ammonium thiocyanate. Put the precipitate along with the filter paper into a conical flask, added to it 30 c.c. of concentrated hydrochloric acid, 20 c.c. of water, 5 c.c. of chloroform and titrated it against standard potassium meta-periodate.

Cuprous thiocyanate reacts with potassium meta-periodate in presence of hydrochloric acid as follows:

$$7\ KIO_4 + 3\ Cu_2(CNS)_2 + 14\ HCl = 7\ KCl + 7\ ICl + 6\ CuSO_4 + 6\ HCN + 4\ H_2O.$$

Hence $$7\ KIO_4 \equiv 3\ Cu_2(CNS)_2 \equiv 6\ CuSO_4 5\ H_2O.$$

A number of titrations were performed and from the volume of standard potassium meta-periodate solution used, corresponding to the end point in each titration, the amount of copper sulphate was calculated. The results are given in Table I.

TABLE I

Copper Sulphate

$CuSO_4 5\ H_2O$ taken. (gm.)	Volume of M/80 KIO_4 used. (c.c.)	$CuSO_4 5\ H_2O$ found. (gm.)
0·0535	20·20	0·0540
0·0722	27·00	0·0722
0·0802	29·90	0·0799
0·0936	35·00	0·0936
0·1069	39·90	0·1067
0·1257	47·10	0·1259

1·00 c.c. M/80 $KIO_4 \equiv$ 0·002674 gm. $CuSO_4 5\ H_2O$.

(2) DETERMINATION OF HYDROGEN PEROXIDE

Hydrogen peroxide reacts with arsenious oxide in alkaline medium (in presence of sodium hydroxide solution) according to the equation:

$$As_2O_3 + 2H_2O_2 = As_2O_5 + 2H_2O.$$

In the determination of hydrogen peroxide, a known excess of arsenious oxide with about 10 c.c. of ten per cent sodium hydroxide was taken in a conical flask and a known volume of approximately $N/10$ hydrogen peroxide run in from burette. The mixture was allowed to stand for a couple of minutes, 50 c.c. concentrated hydrochloric acid, 20 c.c. water, and 5 c.c. of chloroform were added to it. The conical flask was stoppered and the mixture was vigorously shaken. The excess of arsenious oxide, left unreacted in the mixture, was determined by titrating it against standard potassium meta-periodate solution. The reaction is represented as follows:

$$3\ As_2O_3 + 2\ KIO_4 + 4\ HCl = 3\ As_2O_5 + 2\ KCl + 2\ ICl + 2\ H_2O.$$

Table II presents the results of the titrations.

TABLE II

Hydrogen Peroxide

Amount of H_2O_2 taken. (gm.)	Volume of M/60 As_2O_3 added. (c.c.)	Volume of M/60 KIO_4 used. (c.c.)	Volume of M/60 As_2O_3 used for H_2O_2. (c.c.)	Amount of H_2O_2 found. (gm.)
0·0155	20·00	10·90	9·10	0·0155
0·0264	30·00	14·50	15·50	0·0263
0·0387	40·00	17·30	22·70	0·0386
0·0465	45·00	27·60	27·40	0·0466
0·0535	45·00	13·55	31·45	0·0535
0·0697	50·00	9·10	40·90	0·0695

1·00 c.c. of M/60 $As_2O_3 \equiv$ 0·00170 gm. H_2O_2.

(3) Determination of Dioxides of Lead and Manganese

Potassium iodide reacts with the dioxides in presence of concentrated hydrochloric acid:

$$2\ KI + 2\ PbO_2 + 8\ HCl = 2\ PbCl_2 + 2\ KCl + 2\ ICl + 4\ H_2O,$$
$$2\ KI + 2\ MnO_2 + 8\ HCl = 2\ MnCl_2 + 2\ KCl + 2\ ICl + 4\ H_2O.$$

In concentrated hydrochloric acid, potassium iodide reacts with potassium meta-periodate:

$$3\ KI + KIO_4 + 8\ HCl = 4\ KCl + 4\ ICl + 4\ H_2O.$$

A known weight of the dioxide was taken in a conical flask and a known excess of potassium iodide solution was added to it. The mixture was acidified with 50 c.c. of concentrated hydrochloric acid to keep its normality between 4*N* and 7*N*. The excess of potassium iodide was titrated back with standard potassium meta-periodate. About 5 c.c. of chloroform was added to the mixture before each titration to determine the end point. The results are summarised in Tables III and IV.

Table III

0·0350	30·00	19·30	10·70	0·0349
0·0440	30·00	16·50	13·50	0·0440
0·0561	35·00	17·80	17·20	0·0561
0·0685	40·00	19·00	21·00	0·0685

1·00 c.c. M/80 KI ≡ 0·003262 gm. MnO_2.

(4) Determination of Formates

A formate reduces mercuric chloride to mercurous chloride:

$$HCOONa + 2\ HgCl_2 = Hg_2Cl_2 + NaCl + HCl + CO_2.$$

In presence of concentrated hydrochloric acid, potassium meta-periodate oxidizes mercurous chloride to mercuric chloride:

$$KIO_4 + 8\ HCl + 3\ Hg_2Cl_2 = 6\ HgCl_2 + KCl + ICl + 4\ H_2O.$$

A known weight of sodium formate was taken in a conical flask. Some sodium acetate solution, an excess of saturated mercuric chloride solution and enough of water to make the volume to about 75 c.c. were added to it. The mixture was heated on a steam bath for about two hours until the whole of carbon dioxide was evolved. The flask was cooled and the precipitated mercurous chloride was filtered. The precipitate along with the filter paper was transferred to a conical flask, about 50 c.c. of concentrated hydrochloric acid and 5 c.c. of chloroform were added and the mixture titrated against standard potassium meta-periodate. The results are given in Table V.

Table V

Sodium Formate

Amount of HCOONa taken. (gm.)	Volume of M/60 KIO_4 used. (c.c.)	Amount of HCOONa found. (gm.)
0·0400	11·70	0·0398
0·0680	20·30	0·0690
0·0800	23·80	0·0809
0·1000	30·00	0·1020
0·1200	36·00	0·1224

$KIO_4 \equiv 3\ Hg_2Cl_2 \equiv 3\ HCOONa$

1·00 c.c. M/60 $KIO_4 \equiv 0{\cdot}003396$ gm. HCOONa.

(5) Determination of Sodium Sulphide

Sodium sulphide reacts with arsenious oxide in presence of dilute hydrochloric acid according to the equation:

$$3\ Na_2S + As_2O_3 + 6\ HCl = As_2S_3 + 6\ NaCl + 3\ H_2O.$$

Arsenious oxide is oxidized to arsenic oxide by potassium meta-periodate in presence of concentrated hydrochloric acid:

$$3\ As_2O_3 + 2\ KIO_4 + 4\ HCl = 3\ As_2O_5 + 2\ KCl + 2\ ICl + 2\ H_2O.$$

1·50 gm. of sodium sulphide were dissolved in 100 c.c. of water and a known excess of arsenious oxide (2·5070 gm.) dissolved in sodium hydroxide were added to it. The mixture was thoroughly stirred and acidified with hydrochloric acid, when yellow precipitate of arsenious sulphide was formed. The precipitate was filtered, washed with water and the filtrate made up to 250 c.c. To determine the excess of arsenious oxide present in the filtrate, 20 c.c. of the filtrate was mixed with about 30 c.c. concentrated hydro-

chloric acid, 5 c.c. chloroform and titrated against M/60 potassium meta-periodate. The results are tabulated in Table VI.

TABLE VI

Sodium Sulphide

Amount of Na_2S taken.	Volume of the filtrate taken for titration.	Volume of M/60 KIO_4 used.	Amount of As_2O_3 in 250 c.c. filtrate.	Amount of As_2O_3 reacted with Na_2S.	Amount of Na_2S found.
(gm.)	(c.c.)	(c.c.)	(gm.)	(gm.)	(gm.)
1·5000	20·00	20·00	1·2375	1·2695	1·5000
	20·00	20·05			
	20·00	20·00			
	20·00	20·00			

1·00 c.c. M/60 $KIO_4 \equiv$ 0·00495 gms. $As_2O_3 \equiv$ 0·00585 gm. Na_2S.

(6) DETERMINATION OF POTASSIUM IODIDE IN IODINE SOLUTION.

A known volume of iodine solution was titrated against standard sodium thiosulphate, using starch as an indicator. From these titrations, normality of the solution with respect to iodine was calculated.

In presence of concentrated hydrochloric acid, iodine and potassium iodide react with potassium meta-periodate according to the following equations:

$$3\ I_2 + KIO_4 + 8\ HCl = 7\ ICl + KCl + 4\ H_2O.$$

$$3\ KI + KIO_4 + 8\ HCl = 4\ ICl + 4\ KCl + 4\ H_2O.$$

To determine total normality of the iodine solution with respect to iodine and potassium iodide, its known volume was titrated against M/60 KIO_4 in presence of hydrochloric acid and chloroform.

From these two sets of titrations, normality of potassium iodide and its amount in the iodine solution were calculated. The results are given in Table VII.

TABLE VII

Potassium Iodide in Iodine Solution

Amount of KI present in litre of Iodine solution.	Volume of M/60 KIO_4 used.	Normality of I_2 from Thio-sulphate titrations.	Normality of I_2 and KI from KIO_4 titrations.	Normality of KI calculated	Amount of KI found in litre of Iodine solution.
(gm.)	(c.c.)	(N)	(N)	(N)	(gm.)
8·210	13·00	0·0310	0·1300	0·0990	8·217
9·760	19·30	0·0310	0·1485	0·1175	9·752
12·210	17·80	0·0310	0·1780	0·1470	12·200
16·350	22·80	0·0310	0·2280	0·1970	16·350
18·350	25·20	0·0310	0·2520	0·2210	18·350

From the above results given in Tables from I to VII, it is evident that potassium meta-periodate can be used as a volumetric reagent to estimate indirectly copper sulphate, hydrogen peroxide, dioxides of lead and manganese, sodium formate, sodium sulphide and potassium iodide in iodine solution.

The authors are indebted to Dr. Vishwa Nath, Principal, Government College, Hoshiarpur, for providing facilities for the research work.

STUDIES ON THE HARIANA BREED OF CATTLE

By G. P. Sharma,* K. N. Vali *and* K. R. Suri,

Animal Genetics Section, Government Livestock Farm, Hissar

Introduction

Cattle play an important rôle in the agricultural production of our country. They supply much of the power on farms for ploughing and for the transport of agricultural produce to the market. They also transform the rough feed into manure which is so essential for the maintenance of soil fertility. Furthermore they supply the much needed animal protein to a large section of the population in the form of milk and milk products. However, in spite of the fact that we have 38 million heads of milch cattle their milk production is so low that we can provide a *per capita* consumption of 5 ozs. only in most of the States of the Indian Union as against the desirable minimum nutritional quantum of 1 lb. per head. To provide this and for rearing healthy calves it is essential that our total milk production should be increased more than three times. There is, therefore, an increasing demand for the 'dual purpose' animal the progeny of which should be suitable both for 'draught and milk' and not for 'beef and milk' as the term 'dual purpose' is understood in the Western countries. This demand we hope to meet by putting more milk in some of our best draught breeds by careful selective breeding.

With the same object in view the Indian Council of Agricultural Research started some years ago two research schemes—one at the Government Livestock Farm, Hissar, and the other at the Pattagar's Farm at Palayakottai. The breed of cattle maintained at Hissar is Hariana and that at Palayakottai is Kangayam. At both these places an effort is being made to increase the milk yield of these breeds without deteriorating the draught quality which has already been established in them. During the course of our investigations at Hissar we have collected a good deal of valuable data which we propose to record in the following few pages.

Material and Method

As has been stated already the experimental animals at Hissar are of the Hariana breed. The home of this breed is what is popularly known as the 'Hariana tract'. It comprises the districts of Rohtak, Hissar, Gurgaon, part of Karnal and the Delhi State. Pure Hariana animals are found in large numbers in Jhajjar and Rohtak tehsils of the Rohtak district. The cattle of Hissar district are provided with loose thick skin, long sheath, large dewlap, long and thick horns and big drooping ears. They can be

* Now University Reader in Zoology, Panjab University College, Hoshiarpur.

easily differentiated from the pure Hariana animals which have a long and narrow face with flat forehead and a well marked bony prominence at the centre of the poll. They have short horns, small ears, fine thin skin closely adhering to the body, a small dewlap and a small sheath. The bullocks of the Hariana breed are excellent for draught purposes particularly for fast ploughing and road transport. The cows are moderate milkers. Pedigree herds of this breed are maintained at this farm.

Our experiment was originally started in 1944-45 with a female stock of 230 animals (150 heifers of nearly the same age and 80 dairy cows varying in age). All these animals were so selected that they had a certain standard of body conformation of the Hariana breed. No care was taken to select heifers or cows with good udders or with other body points which are generally looked for while judging a milch cow. Ten young bulls conforming to the Hariana breed were also selected in a similar way. In order to have sufficient variability in our experimental herd five of these bulls were purchased from the Hariana tract while the rest were taken from the farm-bred stock. This whole lot of animals was divided at random into ten groups or families and thus each family had 23 females and one male for breeding.

As far as practicable standard conditions of housing, feeding and management are being provided to the experimental herd.

Results

Sex Ratio.—As a result of breeding in the various families all the females (heifers as well as cows) in the original experimental herd have calved at least once since the beginning of the experiment in 1944-45. In all 691 births of calves have been recorded up to the close of March, 1951. Out of these 352 are male and 339 female calves. From these figures the overall sex ratio (i.e. the number of males for every 100 females) is calculated to be 103·83.

Gestation Period.—There were 517 normal births for each of which the exact date of service was known. It was, therefore, quite easy to calculate the gestation period in each case. The frequency distribution of these gestation periods is presented in Table 1.

Table 1.

Frequency distribution of the gestation periods (in days) for all births.

Class Interval	Class value	Frequency
265–269	267	4
270–274	272	8
275–279	277	17
280–284	282	64
285–289	287	156
290–294	292	156
295–299	297	69
300–304	302	19
305–309	307	10
310–314	312	14
	Total ..	517

On further analysis of the data the mean (with error) of all the gestation periods studied worked out to be 290·15±0·22 days irrespective of the sex of calf born. The corresponding figures for some other Indian and foreign breeds of cattle are:—

Kangayam	.. 285 days (Littlewood, 1937).
Ongole	.. 289·1 days (Littlewood, 1937).
Red Sindhi	.. 283 days (Dave and Singh, 1934).
Jersey	279 days (Wing, 1899). 278·51 days (Copeland, 1930). 278·88±0·176 days (Knoop and Hayden, 1934).
Holstein-Friesian	280 days (Wing, 1899). 278·90 days (Knott, 1932). 278·15±0·154 days (Knoop and Hayden, 1934).
Durham or Improved Short-horned breed	283 days (Spencer, 1840).

For the various other breeds of cattle, reference may also be made to the 'Gestation Periods' compiled by Kenneth (1947).

As early as 1840 the Right Hon. Earl Spencer published some tables from which it appears that the male calf is carried by the dam one to three days longer than the female. However, some of the later workers like Wing (1899) are of the opinion that the average period of gestation is the same regardless of the sex of the offspring. In view of these conflicting accounts in the literature we prepared Tables 2 and 3 showing the frequency distribution of the gestation periods for male and female births separately.

TABLE 2.

Frequency distribution of the gestation periods (in days) for male births.

Class Interval	Class Value	Frequency
265–269	267	2
270–274	272	6
275–279	277	3
280–284	282	24
285–289	287	65
290–294	292	81
295–299	297	49
300–304	302	11
305–309	307	4
310–314	312	7
	TOTAL ..	252

TABLE 3.

Frequency distribution of the gestation periods (in days) for female births.

Class Interval	Class Value	Frequency
265–269	267	2
270–274	272	2
275–279	277	14
280–284	282	40
285–289	287	91
290–294	292	75
295–299	297	20
300–304	302	8
305–309	307	6
310–314	312	7
	TOTAL ..	265

From these two tables the average gestation period for male births works out to be 291·11±0·47 days and for female births 289·19±0·46 days. It will be of interest to note that the difference of about two days between the mean gestation periods for male and female births is statistically significant at 5% level of significance. This clearly indicates that the sex of calf has a significant influence on the gestation period in cattle.

Age at first calving.—For this study the data were available only for 182 cows. These data are presented in Table 4 given below.

TABLE 4.

Frequency distribution of the age at first calving (in days).

Class Interval	Class Value	Frequency
1250–1299	1274·5	3
1300–1349	1324·5	2
1350–1399	1374·5	8
1400–1449	1424·5	2
1450–1499	1474·5	15
1500–1549	1524·5	21
1550–1599	1574·5	34

1700–1749	1724·5	15
1750–1799	1774·5	7
1800–1849	1824·5	8
1850–1899	1874·5	7
1900–1949	1924·5	3
1950–1999	1974·5	2
2000–2049	2024·5	2
	TOTAL ..	182

On analysis of the above data the average age (with error) at first calving is found to be 1618·18±10·53 days, i.e. about 4 years and 5 months.

Calving interval.—There were 443 cases in which the interval between two successive calvings could be studied. The data for this study are tabulated below in Table 5.

TABLE 5.

Frequency distribution of the interval (in days) between two successive calvings.

Class Interval	Class Value	Frequency
300–324	312	4
325–349	337	12
350–374	362	19
375–399	387	23
400–424	412	32
425–449	437	31
450–474	462	33
475–499	487	26
500–524	512	40
525–549	537	33
550–574	562	30
575–599	587	37
600–624	612	32

57–59	58	29
60–62	61	32
63–65	64	15
66–68	67	11
69–71	70	3
72–74	73	2
75–77	76	1
78–80	79	1
	TOTAL ..	249

TABLE 8.

Frequency distribution of the birth weight (in lbs.) of female calves.

Class Interval	Class Value	Frequency
30–32	31	1
33–35	34	2
36–38	37	2
39–41	40	14
42–44	43	15
45–47	46	15
48–50	49	65
51–53	52	34
54–56	55	51
57–59	58	18
60–62	61	30
63–65	64	6
66–68	67	3
69–71	70	1
72–74	73	1
	TOTAL ..	258

The statistical analysis of the data presented in the above two tables shows that the average birth weight (with error) for male calves is 53·98 ±0·47 lbs. and for female calves is 52·04±0·42 lbs. This difference of about 2 lbs. between the mean birth weights of male and female calves is statistically significant at 5% level of significance. This indicates that the sex of calf has a significant influence on the birth weight of calves, the male calves being heavier than the female calves.

Effect of Season on Calving

Hammond (1927), in his study of the breeding season, has reported the percentage of cows which calve in different months of the year. From this study which is based on a bulk of statistics collected from various authorities on a fairly large number of cows it is obvious that in the foreign breeds maximum number of cows calve in spring and minimum in autumn months. After further investigations Hammond concludes that the seasonal effect on the distribution of calvings is marked mostly due to the intensity of the reproductive force which is maximum in summer months and minimum in winter months.

Joseph and Dave (1931) have published a table based on 1,553 calvings showing the effect of season on the frequency of calvings in Montgomery cows. According to them the distribution of calvings at Pusa Cattle Farm is, more or less, fairly uniform. Thus their finding runs contrary to that of Hammond.

Sikka (1931), as a result of his observations on 1,274 cows of the Military Dairy Farm, Ferozepore, has published a table for studying the effect of season on the frequency of calvings. He concludes 'that percentage of calvings for different months goes on increasing quite regularly from October, in which month only 5·26% of the total calved, to March, calving 16·01% of the total. From this there is a steady decline till September-calving 3·30%, the lowest for the year. This means that in these herds largest number of cows calve in spring and smallest in autumn months.' This result is in close agreement with that of Hammond.

In view of these conflicting accounts in the literature the data presented in Table 9 showing the monthly distribution of calvings in the experimental herd for the period 1946–51, were collected.

Table 9.

Monthly distribution of calvings.

Months	Feb.	March	April	May	June	July	Aug.	Sep.	Oct.	Nov.	Dec.	Jan.	Total
Season	Spring			Summer			Autumn			Winter			
No. of calvings	78	104	73	51	52	52	35	48	30	42	62	64	691
% of calvings	11·3	15·1	10·6	7·4	7·5	7·5	5·1	6·9	4·3	6·1	8·9	9·3	

From the above table it is clear that the percentage of calvings goes on increasing steadily from November (6·1%) to March (having a maximum of 15·1% of the total calved). After this there is a decline till October (calving 4·3%, the lowest of the year). These observations indicate that the largest number of Hariana cows calve in spring and smallest in autumn months. In order to confirm that the greater or smaller incidence of calvings during these seasons is not due to chance causes, a statistical study was also made. For this purpose comparisons between the means of spring months and other months and between the means of autumn months and other months were made separately. The results are as follows:—

(*a*) Mean of Spring months = 85·00
Mean of other months = 48·45

$$t_{(10)} = \frac{85{\cdot}00 - 48{\cdot}45}{\sqrt{69{\cdot}95}} = 4{\cdot}38$$

Probability for getting such a value of t is less than ·01.

(*b*) Mean of Autumn months = 37·67
Mean of other months = 64·23

$$t_{(10)} = \frac{64{\cdot}23 - 37{\cdot}67}{\sqrt{133{\cdot}54}} = 2{\cdot}30$$

Probability for getting such a value of t is less than ·05.

The above results clearly show that the average number of calvings during spring and autumn seasons is significantly greater and smaller respectively, thereby confirming the views expressed already by Hammond (1927) and Sikka (1931).

We are, therefore, of the opinion that even though the agricultural conditions are poor during summer season at the Govt. Livestock Farm, Hissar, yet the reproductive force is at its maximum partly due to high atmospheric temperature and partly due probably to greater light on account of longer days during this season. The conception rate is, therefore, maximum during the summer season and it results in a larger number of calvings in the succeeding spring season. On the other hand the winter season gives a reverse picture resulting in fewer calvings in the succeeding autumn season. What other factors are responsible for the varying frequency of calvings during various seasons and whether we could regard the temperature as the prime factor in determining the rate of conception, are all points for further research and investigation.

Milk Performance

The lactation-wise milk performance of the experimental herd for the period 1-4-46 to 31-3-51 is tabulated in Table 10.

TABLE 10.

Milk performance of the experimental herd during the period 1-4-46 *to* 31-3-51.

Lactation No.	No. of cows	Average No. of days in milk	Average total yield in lbs.	Average maximum yield in lbs.	Average daily yield in lbs. during lactation
1st ..	133	251·9	1284·9	7·9	4·8
2nd ..	139	274·9	1782·7	10·1	6·1
3rd ..	107	306·1	1780·6	10·4	5·9
4th ..	71	282·3	1675·5	10·1	5·8
5th ..	39	290·2	1827·0	10·0	5·8
6th ..	17	307·9	2077·1	11·9	6·6
7th ..	9	360·9	1972·8	9·9	5·5
8th ..	2	280·0	1553·0	13·5	5·8
TOTAL ..	517				

The average milk yield, irrespective of the order of lactation, works out to be 1749·50±40·25 lbs.

SERVICE PERIOD

To find out the length of the service period (i.e. the interval between the date of calving and the next date of fertile service) the data shown in Table 11 were collected.

TABLE 11.

Frequency distribution of the service period (in days).

Class Interval	Class Value	Frequency
Up to 49	24·5	7
50– 99	74·5	35
100–149	124·5	40
150–199	174·5	55
200–249	224·5	56
250–299	274·5	45
300–349	324·5	51
350–399	374·5	35
400–449	424·5	11
450–499	474·5	7
	TOTAL ..	342

The analysis of the above data shows that the average service period (with error) is 233·71±5·74 days.

Dry period.—Data were also collected to find out the average dry period for the Hariana breed of cattle. These are tabulated below in Table 12.

TABLE 12.

Frequency distribution of the dry period (in days).

Class Interval	Class Value	Frequency
50– 99	74·5	5
100–149	124·5	42
150–199	174·5	66
200–249	224·5	63
250–299	274·5	74
300–349	324·5	48
350–399	374·5	32
400–449	424·5	16
450–499	474·5	5
500–549	524·5	4
550–599	574·5	4
	TOTAL ..	359

On analysis of the above data we find that the average dry period (with error) in this breed is 258·21 ± 5·38 days.

REACTION TIME

Studies for the 'Reaction time' (i.e. the time interval between the bringing of a bull to the cow on heat and the actual time of ejectment) were also made for two years on the ten breeding bulls for the services they performed. The average 'Reaction time' ranges from 5 minutes and 3 seconds to 41 minutes and 11 seconds with an overall average of 23 minutes and 55 seconds ± 3 minutes and 9 seconds. The analysis of variance of the 'Reaction time' of these ten bulls is tabulated below in Table 13.

TABLE 13.

Analysis of Variance.

Source	S.S.	D.F.	M.S.	F. Ratio
Between Bulls ..	29,564,613·12	9	3,284,957·01	2·116*
Within Bulls ..	240,596,694·13	155	1,552,236·7	
TOTAL ..	270,161,307·25	164		

* Significant at 5% point.

The above table shows that the difference between the mean 'Reaction times' of these ten breeding bulls is statistically significant.

As has been stated already two types of bulls have been used for breeding in this experiment. One type is bred at the farm itself and the other is purchased from the Hariana tract. It has been observed that on an average the purchased bulls take only 1064·75 seconds in serving a cow while the farm-bred ones take as many as 1529·04 seconds. This difference of 464·29 seconds in the average 'Reaction times' which may be due to the very

limited exercise for the farm-bred bulls, as a result of stall feeding, has been found to be statistically significant.

Discussion

It will be seen from the foregoing account that for the Hariana breed we have, like the other Indian breeds, very long (i) age at first calving, (ii) calving interval, (iii) service period, (iv) dry period and (v) 'Reaction time'. All these factors contribute to the poor performance of our cattle. It is mainly because of them that we have not so far been able to make dam-daughter comparison at Hissar. Out of a total grown up female progeny of 131 only 75 heifers have so far been mature enough to be served. From these 31 have calved and 5 have completed their respective lactations. Thus in spite of the fact that more than six years have passed we are still not in a position to say anything about the transmitting ability of our animals in the original experimental herd. On the other hand most of the foreign breeds of cattle mature at a much earlier age and thus we can know about their transmitting abilities when they are in the prime of their life. To illustrate our point we give below a comparative account of the age of proving a bull in England and in India.

	England		India	
	Year.	Month.	Year.	Month.
Age of bull when he starts first service	1	6	3	6
Calf is born at	0	10	0	10
This calf becomes mature and receives bull at	1	6	3	6
Gestation period	0	10	0	10
End of first lactation	0	10	0	10
,, ,, second ,, ..	..	..	1	6
Total ..	5	6	11	0

In England a vast majority of heifers prove their quality in the first lactation but, as is apparent from our Table 10, the heifers in India do not show their milk quality in the first lactation. A second lactation has therefore to be taken. Consequently a bull in India has passed the greater part of his effective service life (which is about 13 years) by the time we are able to estimate his transmitting ability. It is mainly because of these factors that we have few, if any, proven sires in India.

To bring about a change in this deplorable state of affairs every effort should be made to lower the age at maturity of our cattle. This should be possible by selective breeding accompanied by better feeding and management as has been achieved in the Sahiwal herd of cattle at the Indian Agricultural Research Institute. Maximum advantage should also be taken of the latest biological technique of artificial insemination for the improvement of our cattle.

Summary

In this paper some interesting details about the Hariana breed of cattle are given. These are:—

1. The Sex Ratio is 103·83.

2. The average gestation period is 290·15±0·22 days for all births. The sex of calf has a significant influence on the gestation period and therefore for male births the gestation period is 291·11±0·47 days and for female births it is 289·19±0·46 days.

3. The average age at first calving is 1,618·18±10·53 days.

4. The average calving interval is 530·85±5·41 days.

5. The average weight at birth of calves, irrespective of the sex of calf, is 52·90±0·34 lbs. The sex of calf has a significant influence on the birth weight of calves, the male calves being heavier than the female calves. The average birth weight for male calves is 53·98±0·47 lbs. and for female calves is 52·04±0·42 lbs.

6. More calves are born during the months of February, March and April and less during the months of August, September and October. It is, therefore, concluded that season has some influence on the frequency of calving.

7. The average milk yield, irrespective of the order of lactation, is 1,749·50±40·25 lbs. The lactation-wise milk performance of the herd is also given in this paper.

8. The average service period is 233·71±5·74 days.

9. The average dry period is 258·21±5·38 days.

10. The average 'Reaction time' ranges from 5 minutes 3 seconds to 41 minutes and 11 seconds with an overall average of 23 minutes and 55 seconds ± 3 minutes and 9 seconds. On an average the bulls purchased from the Hariana tract take only 1,064·75 seconds in serving a cow while the farm-bred ones take 1,529·04 seconds.

PREPARATION OF ACTIVE CARBON FROM A FEW INDIGENOUS SOURCES AND COMPARATIVE EFFICIENCY OF DIFFERENT ACTIVATION TREATMENTS

By Balwant Rai Puri, M. L. Lakhanpal, *and* Balvir Varma

(*Department of Chemistry, Punjab University College, Hoshiarpur*)

Diverse methods of preparing active carbon have been developed in comparatively recent times. These may be divided, broadly speaking, into two categories. In the first category are included what are known as 'chemical processes' in which the carbonaceous materials or sometimes their chars are impregnated with one or more of a variety of chemicals, such as zinc chloride, alkali carbonates, sulphates, sulphuric acid, phosphoric acid, etc., and then carbonized or heated to a high temperature, as the case may be. In the second category of treatments known as 'gas activation processes', charcoal is heated to some temperature between 350° and 1000°C with steam, CO_2, O_2, Cl_2, etc. (1, 8, 12, 16). Steam, which is more commonly used for this purpose, is known to produce maximum activation at temperatures around 1000°C (19) and to be ineffective below 800°C (8) and above 1100°C (10). For steam treatment to be successful the temperature of carbonization should not exceed 600°–650°C (17).

The mechanism of activation is not generally agreed upon. At least three theories have been advanced to explain activation of charcoal by chemical reagents. One of these (2) explains activation as due to catalytic decomposition of residual hydrocarbon complexes, second one as due to enclosure of carbon particles by salt which is subsequently extracted to provide a greater surface area (9) while a third one is based on the dissolution of cellulose by zinc chloride, etc. (6). As regards gas activation Knight, Garner, and McKee (13) consider it to be caused by appreciable increase in surface area of charcoal while Chaney (7) is of the opinion that the adsorbed hydrocarbons are burnt away in this process releasing thereby the active carbon base. Allmand and co-workers (3) suggest that the process simply consists in cleaning up the charcoal surface of the tarry materials.

It appears from perusal of literature that while different methods of activation have been known and several theories have been advanced to explain the mechanism of activation, no systematic investigation has been undertaken to compare the relative merits of the various activation processes. In the present paper the study of the relative effects of three representative and well-known methods of activation on the adsorptive and decolorizing properties of five specimens of charcoal prepared from some common raw-materials has been made with a view to assess the

relative efficiencies of these treatments. The results obtained also give some insight into the mechanism of activation.

Experimental

Raw Materials.—Three out of the five raw materials selected for this investigation were different varieties of wood, namely acacia wood, pine wood and cotton stalk. Coconut shell and sugar were the two other starting materials. Sugar was carbonized by sulphuric acid and then washed free of sulphate ions. The rest of the materials were carbonized by heating them in small pieces in closed vessels between 550°–600°C. The chars in each case were ground and screened through 100 mesh sieve.

Activation.—The following methods of activation were tried :—

1. *Activation by Phosphoric Acid.*—Charcoal was made into a paste with phosphoric acid and allowed to stand for about 30 minutes. The mass was then broken into small lumps, dried in an electric oven and then placed in a silica tube, 1″ wide and 30″ long, and heated in an electric furnace to about 950°C in an atmosphere of nitrogen (4) for 9 hours. The mass was subsequently cooled, washed once with hydrochloric acid, then with water to remove chloride ions, and finally dried at 120°C in an electric oven.
2. *Activation by Zinc Chloride.*—Charcoal was agglomerated with 50% solution of zinc chloride and heated to 650° for 5 hours in a closed vessel provided with a few small holes near the top to serve as exit for the products of volatilization (20). The mass was cooled, washed first with dilute HCl, then with water and finally dried at 120°C.
3. *Activation by Steam.*—A silica pipe, 30″ long and 1″ wide, was filled three-fourths with charcoal and heated to about 950°C in an electric furnace, steam being passed continuously over the charge. As complete information regarding optimum time for steam activation was not available from the literature, a few preliminary experiments were performed to see the influence of the time of activation on moisture as well as methyl alcohol vapour adsorption. It was found that the intensity of adsorption increased with increase in the time of activation up to 10 hours after which it began to decrease gradually. Steam treatment was, therefore, restricted to 10 hours in all the charcoals.

Properties Examined.—The following properties of the activated as well as unactivated materials were examined:—

(i) Adsorption of water and methyl alcohol vapours.
(ii) Adsorption of iodine and potassium permanganate from solutions.
(iii) True density, bulk density and pore space.
(iv) Wettability by water, methyl alcohol, acetone and benzene.

Results

(i) *Adsorption of Water and Methyl Alcohol Vapours.*—0·5 gram portions of the various adsorbents, weighed in small watch glasses, were kept in desiccators containing sulphuric acid-water or methyl alcohol-glycerine mixtures corresponding to different relative vapour pressures of water or methyl alcohol, as the case may be. The increase in weight was determined when it became constant which required about 4 or 5 days time. The results are given in Tables I and II.

(ii) *Adsorption of Iodine and Potassium Permanganate from Aqueous Solutions.*—These tests are reported to be indicative of the ability of a charcoal to remove odours and flavours as well as colloid and colour bodies from solutions (14). The procedure used in these determinations was similar to the one described by Mantell (14). In brief, iodine adsorption was measured by mixing 0·5 gram of charcoal with 30 ml. of 5% HCl solution and 150 ml. of 0·05 *N* iodine solution and allowing it to stand for 24 hours with occasional shaking by hand. Fifty ml. of the supernatant liquid was then titrated against a standard sodium thiosulphate solution, using starch as indicator. Permanganate test was performed by mixing 0·5 gram of charcoal with 100 ml. of 0·5 *N* $KMnO_4$ solution and allowing the mixture to stand for 24 hours with occasional shaking and then titrating an aliquot portion of the supernatant liquid against a standard oxalic acid solution.

The results of these determinations are given in Tables III and IV.

3. *Density, Bulk Density and Pore Space.*—Density was determined by the pyknometer method using methyl alcohol as the immersion liquid. Bulk density was determined by dividing the weight of the dry material that fills a graduated cylinder to the top graduation, on gentle tapping, by the volume of the cylinder. Pore space for 100 gram charcoal, V_p, was calculated by the formula,

$$V_p = 100\left(\frac{1}{D_b} - \frac{1}{D_t}\right),$$

where D_b and D_t are bulk and true densities respectively. The results are given in Table V.

4. *Wettability of Charcoal Surface by Different Liquids.*—Among the properties of porous surfaces that are of scientific and industrial importance the wetting characteristics are particularly significant. These involve measurements of the angle of contact which a porous surface subtends with the wetting liquids.

The height to which a liquid rises in a capillary tube of a solid is given by the well-known relationship,

$$h = \frac{4\gamma}{gd\rho}\cdot\cos\theta,$$

where γ is surface tension and ρ is density of the liquid, d is diameter of the capillary tube and θ is the angle of contact. Cos θ obviously is a measure of the wetting power of the liquid for the capillary surface in question. If, therefore, for a particular porous surface the values of h in the case of

any two liquids of known surface tension and density are h_1 and h_2, then their relative wetting powers for the surface will be given by

$$\frac{\cos\theta_1}{\cos\theta_2} = \frac{h_1\gamma_2\rho_1}{h_2\gamma_1\rho_2}.$$

By means of this equation relative wetting powers of a number of liquids for a particular surface may be expressed with reference to a certain standard liquid whose wetting power ($\cos\theta$) may be taken as unity.

This principle was made use of in determining the relative wetting powers of water, acetone and benzene for the various charcoals with respect to that of methyl alcohol taken as unity. The value of h, the capillary pull, was determined by a simple apparatus described by Mills (15). The results are given in Table VI.

Discussion

Considering the effect of various activation treatments on the moisture adsorption capacity of the charcoals (Table I) it is seen that phosphoric acid treatment produces easily the best products, hygroscopicity increasing appreciably throughout the entire range of vapour pressure. The other two methods of activation, namely treatment with zinc chloride and steam, are far less effective. Comparing these two, however, with one another it is seen that while the former treatment is more effective in the lower vapour pressure range, the latter is more so in the higher vapour pressure range. Since smaller capillary spaces are involved in vapour adsorption at lower vapour pressures and larger ones in adsorption at higher vapour pressures it follows that activation with steam does not result in increasing the number of smaller capillaries and that its cleansing and oxidation action is also confined to the hydrocarbon complexes held up in comparatively larger microspaces only. It is obvious that steam treatment is to be preferred if the object is to remove vapours from atmospheres of higher vapour pressures and zinc chloride treatment if the aim is to remove moisture from atmospheres of lower relative vapour pressures.

The efficiency of the various activation treatments as far as adsorption of methyl alcohol vapours is concerned is shown in Table II. The phosphoric acid treatment is seen again to yield the best materials. The relative superiority of the other two methods is seen to vary with the nature of the charcoal; while zinc chloride treatment is seen to yield better adsorbents in the case of acacia wood and cotton stalk chars, steam treatment is seen to be more successful in the case of coconut shell and pine wood chars. Both the methods, however, are of little consequence in the case of sugar charcoal which gets activated by phosphoric acid treatment only.

Decolorizing properties of the charcoals, as adjudged from iodine and permanganate values (Tables III and IV), are seen to be enhanced appreciably on activation by phosphoric acid and zinc chloride treatments, the former again producing the maximum effect in all the charcoals. Steam, on the other hand, seems to be a poor activator as it causes only a slight improvement in iodine adsorption and actual deterioration in

permanganate adsorption values. It is interesting to note in this connection that while zinc chloride and steam treatments yield somewhat comparable values as far as vapour adsorption properties are concerned their effects on iodine and permanganate adsorption values are so markedly different from each other. Behrman and Gustafson (5) have reported that decolorizing properties of charcoal are favoured by low and hindered by high *p*H values. The cause of low decolorizing properties of steam activated materials appears to lie in their high *p*H values which were found to vary from 6·5 to 7·04 while those for phosphoric acid and zinc chloride activated materials were quite low, varying from 2·12 to 3·47 in the case of different samples. The views of King (11) and Smith, Thornhill and Bray (18) that iodine adsorption depends only upon the total extent of charcoal surface and is independent of its nature does not appear to be quite justifiable. The calculations of surface areas from the results of iodine adsorption (18) therefore should not be considered reliable.

Considering the various adsorption values on the whole (Tables I to IV) it is obvious that phosphoric acid treatment is the best process of activation and that of the various raw materials examined cotton stalks provide the best material for the preparation of active carbon. It is also evident that chars obtained from the three cheap wood sources yield better products on activation, than those obtained from coconut shell and cane sugar and therefore the common belief (14) that chars from nut-shells or fruit pits or sugars provide better materials for activation than the common varieties of wood does not appear to be justifiable. The iodine and permanganate tests were also performed with a commercial sample of 'Decolorizing Charcoal', manufactured by a well-known American firm. The values obtained were 0·579 and 3·02 gms. respectively. The superiority of the charcoals prepared by us is quite obvious (Tables III and IV).

True density is seen to increase and bulk density to decrease (both leading to increased pore space) on activation in all cases (Table V). These changes seem to be closely connected with the increased 'activity' produced in a charcoal. For instance, phosphoric acid treatment which produces the maximum activation also produces the maximum relative increase in true density and maximum relative decrease in bulk density of the various products and just as cotton stalk, acacia wood and pine wood chars get activated to greater extents, so do they suffer greater relative changes in true and bulk density values than sugar and coconut shell chars. It is also significant that cotton stalk char which shows the maximum adsorption undergoes the maximum relative changes in the density values on activation. It appears, therefore, that the effectiveness of activation treatment in a particular case can be broadly assessed from the measurement of the relative changes in true and bulk densities undergone by the material.

Two major factors appear to be responsible for bringing about increased adsorption on activation. They are: firstly cleansing of the charcoal surface of the adsorbed hydrocarbons—and other complexes—which is shown clearly by the increased wettability towards water and decreased wettability towards organic liquids in most of the cases on

activation (Table VI)—and secondly, increase in pore space and internal surface of charcoal (Table V). The cleansing of charcoal surface seems to be brought about by a sort of differential oxidation in which the hydrocarbon and other complexes formed during carbonization and strongly adsorbed by elementary carbon are burnt away, in part or as a whole, thereby releasing the corresponding adsorptive forces. The increase in density which takes place at the same time appears to produce an internal shrinkage resulting in the formation of numerous smaller spaces within the charcoal granules increasing thereby the internal surface area of charcoal.

Summary

Active carbon was prepared from five different carbonaceous materials, including three common varieties of wood, by employing three well-known activation processes. It was found that the method involving the use of phosphoric acid yields the best adsorbents irrespective of the nature of the starting material. The success of an activation process can be assessed from density and bulk density measurements.

Active carbons obtained from cheap wood sources were shown to be better adsorbents than those obtained from coconut shell and cane sugar. The common belief that the latter provide better materials is, therefore, not justified.

Cotton stalks when suitably treated yield excellent adsorbents for vapours as well as for decolorizing properties.

Most of the activated materials showed better decolorizing effects than a commercial 'decolorizing charcoal'.

The changes in the wetting characteristics of charcoal on activation were also measured. There was a tendency for charcoal to become more hydrophillic and less organophillic on activation.

A TABLE OF VALUES OF $N_2(t)$

By HANSRAJ GUPTA, *Panjab University College, Hoshiarpur*

In 1940, I listed numbers [1] less than 20,000 which cannot be represented by Ramanujan's ternary quadratic form:

$$x^2+y^2+10z^2.$$

The table presented here was computed then. It gives the non-negative solutions of the equation:

$$x^2+y^2 = t, \tag{1}$$

with $x \leqslant y$ and $t \leqslant 20{,}000$. If $n_2(t)$ be the number of the non-negative solutions of (1), the solutions (a, b) and (b, a) being considered different when a and b are unequal, then the table gives also the values of $N_2(t)$ defined by the relation:

$$N_2(t) = \sum_{j=0}^{t} n_2(j). \tag{2}$$

If t be the greatest integer, not exceeding k, which is listed in the table, then

$$N_2(k) = N_2(t). \tag{3}$$

The table was of use to me also in computing [2] a 'Table of Values of $N_3(t)$' giving the number of non-negative solutions of

$$x^2+y^2+z^2 \leqslant t, \quad t \leqslant 10{,}000. \tag{4}$$

Evidently

$$N_2(t) = \sum_{j=0}^{[\sqrt{t}]} [\sqrt{t-j^2}] \tag{5}$$

where $[x]$ denotes as usual the integral part of x.

EXPERIMENTS ON THE CONSTITUTION OF CHAKSINE, THE ALKALOID FROM THE SEEDS OF *CASSIA ABSUS* LINN. PART I.*

By S. D. LALA *and* I. SEN GUPTA.

The presence of an alkaloidal principle in the seeds of *Cassia Absus* Linn. was first reported by Dymock[1] and also by Siddiqui[2] *et al.* The latter workers found two water-soluble, isomeric quaternary bases, chaksine and isochaksine and the molecular formula $C_{12}H_{21}O_2N_3$ was advanced for these on the basis of the analysis of chaksine bicarbonate ($C_{12}H_{20}ON_3HCO_3 \cdot \frac{1}{2} H_2O$). Ray[3] *et al.* objected to accept the loss in vacuo at 100° C. to be due to half a molecule of water in the bicarbonate and further due to discrepancy in the percentage of iodine in chaksine iodide. These authors put forward the formula $C_{11}H_{21}O_3N_3$ for chaksine base on the analyses of sulphate, nitrate, chloride and bromide of chaksine which were prepared by them in high state of purity.

This new formula ($C_{11}H_{21}O_3N_3$) was not accepted by Siddiqui[4] *et al.* in a note saying that except for sulphate which melts at 317° C. and is highly incombustible none of the other salts are noted by them to have been dried under vacuo to constant weight before analysis. Neglect of careful dehydration of the salt may have been partly responsible for their low carbon values and further that the halogen value in case of chloride and bromide was not determined.

The present investigation was therefore undertaken to ascertain the molecular formula of chaksine by preparing new compounds of chaksine with various organic acids. A majority of these acids gave well crystalline products by reacting chaksine chloride with the saturated solution of sodium salt of the acid. These products were isolated in a high state of purity and dried thoroughly before analysis. The compounds were analyzed for carbon and hydrogen values only, the estimation of nitrogen value, being useless as it cannot differentiate between C_{11} or C_{12} formula, the molecular weight of both the formula being nearly the same and both having the same number of nitrogen atoms. Our analytical results are in agreement with the molecular formula $C_{11}H_{21}O_3N_3$ for chaksine base, put forward by Ray *et al.* (*loc. cit.*).

In a further communication Siddiqui[5] *et al.* have also reported the preparation of acetate, tartrate, oxalate, succinate and citrate by the action of the acid on bicarbonate or carbonate of chaksine. Out of these acetate and tartrate have been reported to be neutral, whereas oxalate, succinate and citrate are acidic in character due to acid salt formation

* A part of the thesis submitted by one of us (S. D. Lala) for his M.Sc. degree of the Panjab University, Lahore, in December, 1945.

with feebly basic nitrogen. The oxalate, citrate, succinate and other derivatives prepared by us are all neutral in character these being prepared by the action of chaksine chloride with saturated solution of sodium salt of the acid and as such the salt formation with feebly basic nitrogen is not possible. Further, succinic acid being weaker acid than tartaric acid, it is quite surprising that succinic acid should form an acid salt formation as reported by Siddiqui *et al.* (loc. cit.), with feebly basic nitrogen and the reaction with tartaric acid should not give acid salt formation. The analytical results of the compounds support our contention.

Experimental.

Chaksine acetate. ($C_{11}H_{20}O_2N_3CH_3COO$).

Saturated solution of sodium acetate (5 c.c.) was added to 2 gms. of 20% chaksine chloride solution in water. The white precipitate so obtained was filtered after washing several times with water. The product was crystallized from absolute alcohol-ether mixture in colourless needles. m.p. 218–220° C. Found: carbon, 54·55%; hydrogen, 8·3%. $C_{13}H_{23}O_4N_3$ requires: carbon, 54·73%; hydrogen, 8·07%.

Chaksine oxalate. $(C_{11}H_{20}O_2N_3)_2\begin{pmatrix}COO\\|\\COO\end{pmatrix}$.

Saturated sodium oxalate (5 c.c.) was added to 2 gms. of 20% chaksine chloride solution. The white precipitate so obtained was filtered, washed with water and crystallized from water in colourless long needles. m.p. 306–8° d.

Found: carbon, 53·15%; hydrogen, 7·62%. $C_{24}H_{40}O_8N_6$ requires: carbon, 53·33%; hydrogen, 7·40%.

Chaksine malonate. $(C_{11}H_{20}O_2N_3)_2\begin{pmatrix}COO\\\diagdown\\CH_2\\\diagup\\COO\end{pmatrix}$.

Sodium salt of malonic acid was prepared by neutralizing 2 gms. of malonic acid with 10% sodium chloride solution. It was then added to 2 gms. of 20% chaksine chloride solution. The white precipitate after washing with cold water, was crystallized from hot water in beautiful long needles. m.p. 180–82° C. (effer.)

Found: carbon 54·21%; hydrogen, 7·46%. $C_{25}H_{42}O_8N_6$ requires: carbon, 54·15%; hydrogen, 7·58%.

The other derivatives as given in Table I were prepared in similar manner.

From the table it is evident that the percentage of carbon and hydrogen as found by us is quite in agreement with those calculated from Dr. Ray's formula ($C_{11}H_{20}O_2N_3X$) and not with that put forward by Dr. Siddiqui ($C_{12}H_{20}ON_3X$).

The authors take this opportunity to thank Dr. Bashir Ahmad, Ph.D. (London), for his keen interest and encouragement in the work.

THE MILLIPEDE SPERM

By VISHWA NATH *and* GANPATI PARSHAD SHARMA

(*Department of Zoology, Panjab University College, Hoshiarpur*)

PREVIOUS WORK

To the best of our knowledge the earliest work on the sperm of chilognaths is by Gilson (1886), who gave a very brief account of the ripe sperms of *Glomeris marginata, Polydesmus complanatus*, three species of *Julus*, and *Blaniulus guttulatus*. In the last-named species he described a filiform sperm, but in *Julus* he described a cup-shaped sperm reminding one of the Decapod sperm. Judging from the scanty data available Gilson also described a cup-shaped sperm in *Polydesmus complanatus*, although the cup in this form seems to be very shallow as compared with that of the *Julus* sperm. In *Glomeris marginata* he figures a peculiar spindle-shaped sperm in which the nuclear matter, according to the author, gets dispersed in the cytoplasm on the dissolution of the nuclear membrane.

In 1909 Oettinger published a long paper illustrated by many figures on the maturation and formation of spermatozoa in *Pachyiulus varius*. Although this paper deals mainly with chromosomes, the author, in an attempt to prove that the millipede sperm is a normal sperm, has described an axial filament, a sharp point (acrosome?) and a middle-piece. It is very difficult to follow this author, and, in our opinion, most of Oettinger's homologies are wrong.

In 1914 Sokoloff described in *Polyxenus* sp. a diatom-shaped spermatozoon in the male, which, on transference to the receptaculum seminis of the female, becomes transformed into a long, tightly-wound spiral thread. It is difficult to accept this account.

The last paper on the subject is by Warren (1934). In the five species of millipedes examined (*Odontopyge* sp., *Poratophilus diplodontus, Chersastus ruber, Ulodesmus bispinosus* and *Sphaerotherium punctulatum*), Warren described the ripe or semi-ripe spermatozoa as rounded, oval or sub-triangular in front view, and bi-convex (bilateral) or plano-convex or saucer-shaped (unilateral) in edge view, and, according to Warren, they are presumably non-motile. Warren's main object is to show that normal spermatozoa can arise from sex-cells, which have undergone amitosis, and that nuclei without the production of chromosomes may give rise to more than one spermatozoon. Warren is of the opinion that the extent to which amitosis occurs in growing tissues has been gravely underestimated by cytologists through theoretical considerations, and that the general view that amitosis in the metazoa is to be regarded as a degenerate process is not true. 'In the whole course of the investigation of the five

species of millipedes, karyokinesis has not been observed in the case of the nuclei of the walls of the vasa deferentia or reticular ribbon, although many individuals of various ages have been sectioned, and notwithstanding the fact that these nuclei are capable of producing spermatozoa. Mitosis, however, occurs very abundantly in certain of the lateral lobes, but it is remarkable that just those lobes which exhibit it in an unmistakable manner are the ones which ultimately produce abortive spermatozoa or glandular tissue. It would almost appear as if the physiological functions of glandular tissues require karyokinesis, and that mitosis is not necessary for the sex-cells.' (Warren, p. 356.)

All will agree with Warren that his findings, *if true*, will lead to a 'complete reversal of the prevailing views as to the intimate connection of karyokinesis with the determination of sex and the transmission of hereditary characters'. But a careful examination of Warren's script and figures in the light of our own work has convinced us that his conclusions are wholly unwarranted and that he has grossly misinterpreted appearances which are normal in spermatogenesis and with which a student of spermatogenesis is so familiar. Under the chapter on Discussion we shall have occasion to refer to Warren's figures and to show how and where he has erred in the light of our own observations. But here it is necessary to give a summary of Warren's work.

The ground-plan of the male generative organs of the five species of millipedes examined by Warren is as follows:—

On each side of the body, situated ventral to the gut, and immediately above the nerve-cord, are two vasa deferentia extending backwards from the external apertures and ending bluntly at some little distance from the posterior extremity of the body. The right and left vasa deferentia are connected together by a series of regularly spaced transverse tubes, like the rungs of a ladder. The vasa deferentia bear laterally a series of stalked structures, which Warren calls the lateral lobes. In their origin and general appearance these lobes are similar, but they differ in their ultimate fate; some are spermatic lobes and produce sperm, others are of the nature of accessory genital glands, and these glandular lobes may vary among themselves in histological character. Typically the walls of the vasa deferentia and of the transverse connections are capable of producing spermatozoa, and such spermatozoa differ in some respects from those formed in the spermatic lobes. Some of the lobes produce abortive sperm, and the purely glandular lobes which do not form spermatozoa are not all the same. Warren, therefore, concludes that there is a very considerable complexity in the histology and physiological functions of the different parts of the generative organs. As we shall show later on this is a wholly unwarranted conclusion of Warren, who does not seem to be familiar with even the broad outlines of spermatogenesis in general.

According to Warren the sperm-development of all the five species described by him conforms to the same general plan, but each species exhibits some variation and some points of special interest. Thus in *Odontopyge* the histological character of the lateral lobes is particularly diverse—some giving rise to bilateral sperm and others to unilateral sperm,

and others again producing abortive sperm or purely glandular tissue; in *Poratophilus* the lateral lobes, so far as observed, are mostly glandular, but a few produce obviously defective sperm; in *Chersastus* the spermatozoa are all unilateral, and in certain lateral lobes they are produced singly or in 2's, 3's, 4's and occasionally in 5's or even 6's from the cell elements; in *Ulodesmus* the spermatozoa are extremely minute, with a diameter of about 0·7μ; in *Sphaerotherium* the lateral lobes exhibit a simpler condition —some of them produce spermatozoa from special nuclei, while the remaining cell-elements are gradually absorbed as the central mass of sperm increases in size, and the rest of the lobes form only small-celled glandular tissue or degenerate sperm.

Material and Methods

In view of the confused state of literature available on the subject, particularly in view of the revolutionary claims made by Warren, and further, bearing in mind the experience gained in this Laboratory of the non-flagellate sperms of the Decapod Crustacea (Nath, 1932, 1937 and 1942), it was considered profitable to study the sperm of the large millipede, *Thyroglutus malayus*, available at Solan in Simla Hills in the Punjab. Consequently one of us (G.P.S.) paid a visit to Solan in the Summer of 1940 with the object of fixing the male gonads of the millipede.

A plentiful supply of the millipede cannot be obtained till about the middle of August. The males can be easily distinguished from the females by the presence of a pair of dark copulatory appendages on the ventral surface of the 7th segment. The male gonads of *Thyroglutus malayus*, as is usual in the millipedes, are unpaired, consisting of a bunch of grape-like lobes and lying underneath the alimentary canal. They extend almost to the posterior end of the animal.

The testicular material was fixed in Flemming, without acetic, for at least 24 hours and washed in running water for the same period so as to remove all traces of chromic acid and osmic acid. The material was dehydrated as usual and cleared in cedar-wood oil. It was subsequently embedded in paraffin at Lahore in the month of October 1940, and sections were cut 5 to 6 microns thick. These were stained with 0·5% iron-haematoxylin. Bouin's fluid followed by 0·5% iron-haematoxylin was also used as control.

The millipedes were identified as *Thyroglutus malayus* (Carl.) belonging to the order Spirostreptoidea and family Harapagophoridae by the Zoological Survey of India.

Although our investigations were completed by the end of 1941, it has not been possible to go to the press earlier on account of the non-availability of Oettinger's paper in this country. Nor was it possible to obtain it from abroad on account of the war. It was only in 1946 that one of us (G.P.S.) studied Oettinger's paper at Edinburgh where he was sent as State Scholar by the Government of India. From there he sent photographs of Oettinger's figures and an English translation of his (Oettinger's) script to his co-author (V.N.) who prepared the paper for publication at Lahore. Before it could be sent to the press, however,

partition of the country took place and the manuscript along with figures was, therefore, left at Lahore (Pakistan). A few years later the senior author (V.N.), while going through his papers which were sent to him from Pakistan by the courtesy of Dr. Nazir Ahmed, came across the manuscript of this paper, which he had prepared at Lahore. In 1951, while conducting an examination at Allahabad, he also got hold of a slide showing the serial sections of the testicular material of *Thyroglutus malayus*. This had been presented to Dr. Bhattacharya of Allahabad, when he had gone to Lahore to examine the junior author (G.P.S.) for the award of an M.Sc. degree in 1941. The figures presented in this paper have been recently redrawn by the junior author (G.P.S.) from this slide as well as from fresh preparations, which were made by him last year from the testicular material of another large millipede, which is also available in Hoshiarpur.

Observations

Spermatogonia.—As is usual in spermatogenesis the spermatogonia have large vesicular nuclei (Plate I, figs. 1 to 3). The spermatogonial nucleus hardly reveals any structure save for the presence of a nucleolus, which is generally excentric. As revealed by haematoxylin-staining, the nucleolus appears to be of the nature of an amphinucleolus, showing a ground substance of a lightly staining material in which are embedded a number of small deeply staining granules (Plate I, figs. 2 and 3). The presence of a single prominent nucleolus is one of the diagnostic features of a spermatogonial cell.

The mitochondria appear as pale, fine granules in the cytoplasm arranged in the form of a juxta-nuclear mass generally situated opposite the nucleolus (Plate I, fig. 1). They are delicate granules, and they stain so feebly with iron-haematoxylin that it is not always possible to demonstrate them.

In sharp contrast with mitochondria the Golgi elements stain deeply with haematoxylin. They exist in the form of granules, appreciably bigger than the mitochondria, and are generally situated in the vicinity of the nuclear membrane (Plate I, fig. 1). In the fully grown spermatogonia, both the mitochondria and the Golgi elements tend to become circum-nuclear in arrangement (Plate I, fig. 3).

During spermatogonial mitosis the mitochondria and the Golgi elements are more or less evenly sorted out to the two daughter cells (Plate I, fig. 4). In this process it is always possible to follow the sorting out of the mitochondrial granules as they are so numerous, but the Golgi elements, being few in number, are not always so easily traceable. The spermatogonial spindles are not well defined. Each spindle is a fibrillar and fusiform structure with a sharply staining centrosome at each pole (Plate I, fig. 4). Very often the spindle is completely masked by a mantle of mitochondrial granules. Astral rays are conspicuous by their absence.

A testicular lobe consists of many follicles. The spermatogonia studied and described by us are from follicles which do not contain any other kind of sperm-forming cell. At any rate we have never observed

spermatogonia co-existing with spermatocytes or spermatids or sperms in the same follicle.

Each spermatogonial follicle in a testicular lobe is ensheathed by a thick connective tissue covering in which very small nuclei can be seen here and there. A follicle has its own lumen and the lumina of all the follicles in a lobe unite together to open into the vas deferens.

Nurse-cells.—A follicle containing primary spermatocytes or secondary spermatocytes and spermatids in different stages of spermateleosis has invariably a very distinct layer of what we must define as nurse-cells, lying immediately below the outermost sheath of connective tissue.

A nurse-cell is a fairly large cell (Plate I, fig. 5). Its nucleus has a number of not very deeply staining minute granules distributed uniformly. A small nucleolus is also invariably met with immediately under the nuclear membrane.

It seems likely that in a developing follicle the outlying spermatogonia directly form the nurse cells, while the remaining ones form the primary spermatocytes after the usual process of growth. It is hardly necessary to point out that this conclusion is in conformity with what happens in spermatogenesis and even in oogenesis in general.

Primary spermatocytes.—The primary spermatocytes are definitely larger cells than the spermatogonia, their nuclei also being larger (Plate I, figs. 6 to 8). The complete absence of a nucleolus is one of the diagnostic features of the primary spermatocyte in sharp contrast with the prominent nucleolus of a spermatogonium. During early prophase I faintly staining spireme threads appear in the nucleus and the nucleolus seems to be completely broken up into a large number of deeply staining chromatin granules which are generally arranged on the inner surface of the nuclear membrane (Plate I, figs. 6 to 8).

The mitochondria of the primary spermatocyte are granular as in the spermatogonia but, on account of their uniform distribution in the cytoplasm, it is not always easy to demonstrate them. On the other hand, the Golgi elements have a distinct tendency to come together and form fairly big bodies which can be easily demonstrated (Plate I, figs. 6 to 8).

During the first meiotic divisions, beautiful and well-defined spindles can be seen (Plate I, figs. 9 to 11). Like the spermatogonial spindles, these are fibrillar and fusiform structures with a sharply staining centrosome at each pole, but these are definitely bigger. Both the mitochondria and the Golgi elements are seen to be distributed almost evenly to the two daughter secondary spermatocytes.

Secondary Spermatocytes.—Each resting secondary spermatocyte is similar to the primary but it is definitely smaller than the latter (Plate I, fig. 12). The second meiotic divisions are definitely of two kinds, early and late. In the early divisions all cells of a follicle are found to be dividing —some cells are in metaphase, others in anaphase and still others in early or late telophases. In these early second meiotic divisions the spindles are large and the centrosomes are only slightly larger, if at all, than the centrosomes found at the poles of the spindles of the first meiotic divisions (Plate II, figs. 14 to 16). But follicles are often met with in which most of

the cells have gone far beyond telophase II and have already passed through the early stages of spermateleosis. Amongst such spermatids one may come across cells which are still in metaphase II. Two such cells have been drawn in figs. 17 and 18, Plate II. It may be noted that in these figures the spindles are very small and the centrosomes are much more prominent.

The more or less even sorting out of both the mitochondria and the Golgi elements can be seen again during the second meiotic divisions (Plate II, figs. 13 to 18).

Spermateleosis.—In the earliest spermatid, as shown in fig. 19, Plate II, the chromosomes are seen fusing together to form the nucleus. The latter during the resting stage reveals a number of fine chromatin granules inside it (Plate II, fig. 20). In these early spermatids the mitochondria are distributed uniformly throughout the cytoplasm and a few prominent deeply staining Golgi granules are seen here and there. In fig. 19, Plate II, can also be seen another darkly staining granule which is surrounded by a clear area. This is most probably the centrosome. In fig. 20, Plate II, the centrosome has grown fairly big in size and can be easily distinguished from the Golgi elements.

In the ensuing process of spermateleosis important changes take place both in the nucleus and the cytoplasm by means of which the ripe spermatozoon assumes an atypical and saucer-shaped appearance. This important process is heralded by the movement of the centrosome and the nucleus towards the periphery of the cell (Plate II, figs. 21 to 24). As this movement is going on the centrosome grows still bigger in size and ultimately becomes ring-like. In fig. 22, Plate II, a sharply staining granule can also be seen at the junction of the nucleus and the ring-like centrosome. This is the centriole. The wall as well as the contents of the anterior end of the nucleus at this stage start taking up deeper stain than the posterior end (Plate II, figs. 21 to 24). This is the beginning of the formation of a cup-like nucleus. The centrosome now fuses completely with the nucleus and as this also stains intensely it is difficult to make out its real structure. In some of the top views of the maturing spermatids, however, the centrosome can be clearly seen to be in the form of a deeply staining ring with a sharply staining granule or centriole in the centre (Plate II, fig. 27 and Plate III, figs. 28 to 33). Outside the ring-like centrosome there is a clear area, which does not take up any stain. In side views of the maturing spermatids the centrosome generally appears as a slightly compressed and conical body staining uniformly and deeply with haematoxylin (Plate II, figs. 23 and 24). Sometimes, however, the ring-like character of the centrosome may be revealed even in the side views when it may appear as a crescent with a sharply staining granule or centriole at the tip of the cone (Plate II, figs. 25 and 26). The clear area surrounding the centrosome can also be seen just below the crescent.

As the nucleus is attaining its cup-like form small vacuoles appear in the cytoplasm and both the mitochondria and the Golgi elements seem to merge into these (Plate II, figs. 24 to 27 and Plate III, figs. 28 to 30).

When the wide and shallow nuclear cup is completely formed it appears to be quite empty (Plate III, figs. 33 to 42 and Plate IV, figs. 43, 44 and 46 to 48). The chromatin in it is distributed in what we consider a unique manner. The whole of it, in the form of fine chromatin granules, seems to be aggregated just in the mouth of the nuclear cup.

In all these late spermatids the cytoplasm appears frothy due to the presence of a large number of vacuoles. As they always stand out prominently both in smears and sections they seem to have a firm consistency. The mitochondria are still granular but the Golgi elements at this stage have a distinct tendency to come together to form bigger masses (Plate III, fig. 41). Nevertheless, like the mitochondria, they also merge into these vacuoles, and thus no such structure as the acroblast or the acrosome is formed.

By a two-fold process of growth and coalescence the vacuoles in the cytoplasm form a large vesicle, the cytoplasmic vesicle (Plate II, figs. 24 to 27; Plate III, figs. 28 to 30 and 34 to 42 and Plate IV, figs. 43 to 48). In appearance it is structureless and hyaline. Judging from the fact that it never becomes distorted in form in finished preparations it seems to be quite firm. This cytoplasmic vesicle which has a glue-like consistency goes on growing till the entire cytoplasm is absorbed.

Just before the ripe sperm is formed the cytoplasmic vesicle either bursts or is pushed inside the nuclear cup. The shape of the nucleus of the ripe sperm and the arrangement of the chromatin granules in it, however, strongly indicate that the cytoplasmic vesicle is pushed inside the nuclear cup. It will be recalled that in the late spermatids the chromatin granules are arranged uniformly only in the mouth of the nuclear cup, the rest of it being quite empty. In the ripe sperm, however, the chromatin granules can also be seen arranged just beneath the nuclear wall (Plate IV, figs. 50 to 52). This seems to be the result of the entry of the cytoplasmic vesicle into the nuclear cup. It is further proved by a section of the ripe sperm (Plate IV, fig. 49) in which no chromatin granules are seen beneath the nuclear wall. Instead there is only a shaded area which is most probably the cytoplasmic vesicle. Similarly in the top view of a ripe sperm (Plate IV, fig. 53) one can see a ring-like centrosome with a sharply staining granule or the centriole in the centre. Outside the clear area round the centrosome there is a darkish granular area; and a similar dark granular area is seen just inside the outer deeply staining line, which represents the rim of the nuclear cup. Both these darkish areas represent chromatin concentration at the base and the mouth of the nuclear cup, the intervening area being lighter.

The ripe sperm, therefore, is a simple structure, consisting of three cell-elements only, viz., the nuclear cup, the large ring-like centrosome and the cytoplasmic vesicle. The acrosome, the middle-piece and the axial filament of the typical flagellate sperm are conspicuous by their absence.

The rim of the nuclear cup in the very much condensed ripe sperm of *Thyroglutus malayus* or any other millipede is very misleading indeed. In side views it takes up intense stain and appears to be a new structure

that has put in its appearance at the distal end of the cytoplasmic vesicle to plug the mouth of the nuclear cup (Plate IV, figs. 49 to 51). But a careful examination of all the stages in spermateleosis has clearly revealed that this interpretation is wholly wrong. The deeply staining plug-like thing in side views is only the chromatin-rich rim of the nuclear cup along with a portion of the cytoplasmic vesicle which is showing through it.

Mention may be made here of a very fine process on each side of the mouth of the nuclear cup which may sometimes appear in the side view of a ripe sperm (Plate IV, figs. 50 and 51). Such a process has been figured by Gilson (1886) also in the ripe sperm of *Julus*, but he does not make any mention of it in the text. This process is obviously due to the stretching out of the rim of the nuclear cup consequent on the compression of the sperm from side to side.

Lastly we may also refer to the so-called bilateral spermatozoa described by Warren (1934). In fig. 57, Plate IV, we have shown a cell which, according to Warren, will be a bilateral spermatozoon. In reality, however, these are two ripe spermatozoa which have arisen quite normally from their respective spermatids with the only difference that the furrow separating the two daughter spermatids has not so far appeared in this particular secondary spermatocyte. This will be made amply clear if a careful study is made of our figs. 54 to 56, Plate IV. In all these figures it will be noticed that the process of spermateleosis is going on without the complete separation of the daughter spermatids after the second meiotic division. Such a phenomenon has also been noticed in the spider, *Plexippus paykulli* (Sharma, 1950).

Discussion

To sum up: the spermatozoon of *Thyroglutus malayus* is a simple cell, consisting of three cell-elements only, viz., the nucleus, the centrosome and the cytoplasmic vesicle. The nucleus is in the form of a shallow cup with a circular mouth. At the bottom of the nuclear cup lies the ring-shaped centrosome; and the cavity of the nuclear cup is completely filled up by the cytoplasmic vesicle. The result is that the chromatin of the nucleus is not uniformly spread out all over the cup, but is confined to a narrow area just beneath the walls of the nuclear cup. The chromatin-rich rim of the nuclear cup, therefore, appears as a granular disc perforated by the circular mouth in front view (Plate IV, fig. 53) and as a deeply staining transverse bar in side view (Plate IV, figs. 50 and 51). This deeply staining area round the mouth of the nuclear cup has been figured by Gilson (1886) in the side view of the sperm of *Julus* (figs. 770, 771, 773 and 775) and by Warren (1934) in a similar view of the sperm of *Odontopyge* sp. (Pl. XVIII, figs. 26 to 28); but both these authors have not made any attempt to explain what the structure really is.

The mitochondria and the Golgi elements have been followed from the spermatogonium up to the spermatid in *Thyroglutus malayus*; but both these cell-elements degenerate and merge into the cytoplasmic vesicle during spermateleosis.

In its general make-up the millipede sperm closely resembles the Decapod sperm (Nath, 1932, 1937 and 1942), more particularly the sperm of the Macruran forms, *Penaeus indicus* and *Panulirus polyphagus*, except that the centrosome in the millipede sperm is proximal and not distal. The millipede sperm also resembles more particularly the sperm of 19 Brachyuran genera described by Nath, except that in the millipede sperm there is a single centrosome, whereas in the latter there may be two centrosomes in some species and three in others. Other points of resemblance between the millipede sperm and the Decapod sperm are (1) the cup-like nucleus, (2) the presence of a cytoplasmic vesicle which fills up the cavity of the nuclear cup, (3) the absence of an acrosome on account of the complete disappearance of the Golgi material of the spermatid, (4) the absence of a middle-piece, and (5) the absence of the flagellum-like tail.

The details of the process of formation of the cytoplasmic vesicle in *Thyroglutus malayus* seem to be similar to those found in the spermateleosis of many species of Brachyura described by Nath (1932 and 1942). But in *Thyroglutus* the mitochondria are too small and difficult to stain and for this reason it is impossible to be certain whether the vacuoles which appear in the cytoplasm of the spermatid arise *de novo* or they are the mitochondria which become vacuolar as in the Brachyura.

Warren's figures (1934) are generally correct, but his interpretations being grossly inaccurate, he has arrived at startling conclusions, which cannot be allowed to go unchallenged. Warren states that he has seen ripe spermatozoa in the vasa deferentia or reticular ribbon of *Odontopyge* sp. He further states that he failed to see karyokinesis in the case of the nuclei of the walls of these tubes. From this he jumps at the conclusion that 'these spermatozoa in the reticulum have not simply been received from the lateral lobes, but they have originated *in situ*, for isolated islands of developing sperm can be seen in chambers in the tubes, bounded in front and behind by the walls, which may be so swollen that the lumen of the tube is closed (text-fig. 2, *is*).'—(p. 361).

In Warren's text-fig. 2, the 'isolated islands of developing sperm' are *not* 'bounded in front and behind by the walls'; on the contrary these islands of the so-called developing sperm communicate through the lumen of the tubes with the lumen of the lateral lobes. But even if the lumina of the vasa deferentia were temporarily blocked, it certainly does not follow that the sperms found in these tubes 'have originated *in situ*' and have not come from the lateral lobes. Equally unwarranted is the conclusion of Warren that the spermatozoa found in these tubes originate from the nuclei lining them by a process of amitosis, simply because Warren failed to see karyokinesis in the case of the nuclei of the walls of the vasa deferentia. Moreover, Warren's figures of amitosis in the nuclei of the walls of vasa deferentia are unconvincing (e.g., fig. 8, Pl. XVIII).

While describing the genesis of the spermatozoa found in the reticulum (vasa deferentia), Warren has mixed up these tubes with the lateral lobes in which all stages of spermatogenesis can be found. By itself this error perhaps would not have been very serious, but Warren has grossly.

misinterpreted the stages he has seen in the lateral lobes and given a very inaccurate account of spermatogenesis.

Warren repeats that mitosis has not been observed in the vasa deferentia, while describing the genesis of spermatozoa found in these tubes. 'The nuclei of the wall proliferate, and the inner ones subsequently swell by the absorption of cytoplasm. At the same time the swollen nuclei become surrounded by a sharply defined membrane differentiated out of the cytoplasm immediately in contact with them. The structures are rounded but slightly compressed, and thus the future bilateral symmetry is early indicated (Pl. XVIII, figs. 10 to 13). The chromatin becomes dissolved and loses its basophil character, and there appears a somewhat large, central, globular body which entirely fails to stain with Delafield haematoxylin but stains black with iron-haematoxylin (fig. 20). The nature of this body is unknown; possibly it is chondriosomal, but it may provisionally be called plasmosome. Except for the globular body or plasmosome, the substance of the nucleus becomes homogeneous, and it is also neutrophil (fig. 10, *h.n.*; fig. 20).'—(p. 360).

Fig. 20, Pl. XVIII of Warren illustrating the homogeneous and swollen nucleus, which is alleged to have arisen amitotically and forms an entire sperm, is really the front view of the ripe sperm. The so-called plasmosome is really the large centrosome[1], which has taken its position at the bottom of the nuclear cup. The dark outermost circular line in Warren's fig. 20 is the wall of the nuclear cup and the homogeneous body (Warren's nucleus) is really the hyaline structureless cytoplasmic vesicle, which fills up the cavity of the nuclear cup. Similarly the homogeneous nucleus (*h.n.*) of Warren's fig. 10 is most certainly the developing cytoplasmic vesicle.

That Warren has mixed up the sections of the vasa deferentia and the spermatic lobes is clear from his own description of figures. Figs. 10 to 13, Pl. XVIII should be all sections of the vasa deferentia as he is describing the genesis of the spermatozoa of the reticulum, insisting that they originate *in situ* and have not come from the spermatic lobes. And yet in the legend he describes fig. 10 as representing a section of the spermatic lobe. Again figs. 11, 12 and 13 represent, according to the legend, sections of the reticulum tubes, but in the explanation of fig. 13 he talks of primary spermatocytes transforming into bilateral spermatozoa.

Warren gives a most fantastic and inaccurate account of the origin of the so-called bilateral spermatozoa found in the vasa deferentia from a single homogeneous nucleus, which, as we have already shown, is really the cytoplasmic vesicle. On p. 360 Warren continues: 'The plasmosome, *which is really the centrosome*[2], divides into two, and the halves migrate from a central position to the middle of the two opposite, slightly compressed convex surfaces (figs. 21, 22, *P*). An indication of a change in the character of the homogeneous substance is now given by the assumption of a slight

[1] It may be stated here at once that Warren does not make a mention of the centrosome even once in his paper, although he has described and sketched mitotic figures in the lateral lobes.

[2] Italicized part ours.

basophil tendency at the periphery of the two convex surfaces, each of which carries a plasmosome (fig. 23). The compression of the nucleus now increases, and ultimately the structure becomes biconvex lens-shaped (fig. 25). A small eminence[1], often flat-topped, is formed in the centre of the two opposite convex surfaces immediately over the site of the plasmosome.'

These so-called bilateral spermatozoa of Warren are really formed from two sister spermatids, which do not separate for a long time or from a secondary spermatocyte whose nucleus has divided into 2 spermatid nuclei but in which the appearance of the cytoplasmic furrow has been delayed. Warren has himself admitted 'that the bilateral spermatozoa formed in the reticulum fairly frequently split in two symmetrical halves ....'—(p. 361). From a single 'homogeneous nucleus' Warren derives not one spermatozoon (unilateral) but two spermatozoa (bilateral); and he considers the homogeneous nuclei which produce the bilateral structures in the vasa deferentia as equivalent to those of the secondary spermatocytes. This last statement of Warren would be correct if the homogeneous nuclei were not really the cytoplasmic vesicles of mature sperms.

Equally arbitrary is the division of the lateral lobes or spermatic lobes of the testis in six categories in *Odontopyge* sp. Warren has based this division on the histological appearances of the lobes, although 'externally there is no marked difference in the lobes, except that they diminish in size both at the anterior and posterior ends of the series, and the stalk of attachment to the reticular tubes varies in width and length (text-figs. 1, *a*; 2).'—(p. 362). These six classes of lobes are (1) smaller lobes situated mostly at the anterior end of the series and producing bilateral spermatozoa, (2) lobes bearing unilateral spermatozoa, which arise in pairs, (3) large-celled lobes which apparently have a glandular function, (4) lobes producing solitary, unilateral spermatozoa which are apparently non-functional, (5) small-celled lobes of glandular function, and (6) reticular lobes, mainly glandular in function and confined to the more posterior portion of the series.

Warren is obviously ignorant of the manner in which various stages of spermatogenesis are met with in a testis. He does not seem to know that a testicular follicle or lobe will show at different periods all stages of spermatogenesis. He has seen a spermatic lobe in a particular stage and has placed it in a category of its own, not knowing that the contents will change at a later stage. In spite of the very confused account which Warren has given of the spermatic lobes, it is possible to say what stages in spermatogenesis the contents of these lobes represent.

1. *Lobes Producing Bilateral Sperm.*—A reference to Warren's text-fig. 2 and figs. 15 and 16, Pl. XVIII will at once show that the lobes figured there are not special lobes but ordinary lobes containing ripe spermatozoa. In figs. 15 and 16 inactive spermatogonia showing vesicular nuclei are also present towards the periphery of the lobes. As has already been explained

[1] This eminence is really formed by the centrosome.

the so-called bilateral sperms are two sperms arising from two sister spermatids which have not yet separated.

2. *Lobes Bearing Unilateral Sperms in Pairs.*—According to Warren these lobes (Pl. XIX, figs. 41, 50 and 51) may retain a few vesicular nuclei with scattered chromatin grains, and he believes that they are probably special gland cells. On the contrary we believe that the vesicular nuclei are those of the inactive spermatogonia. Fig. 51 shows a large number of spermatogonial nuclei towards the periphery, whereas towards the interior are to be found a large number of cytoplasmic vesicles (Warren's homogeneous nuclei) to each of which is attached either one nuclear cup or two nuclear cups, each nuclear cup having its own centrosome (Warren's plasmosome). By figs. 52 to 61 Warren attempts to illustrate the exact manner in which these spermatozoa arise from 'homogeneous nuclei', but his account is grossly inaccurate. Figs. 52 and 53 really represent spermatogonial nuclei with scattered chromatin grains (Warren's special gland cell nuclei). These nuclei, according to Warren, give rise to 'homogeneous nuclei' as shown in figs. 54 to 61. Now a glance at these figures will show that figs. 54 and 55 represent two separately growing sperms in front view, and Warren has mistaken the cytoplasmic vesicle for the homogeneous nucleus, the centrosome for the plasmosome, whereas the real nucleus is indicated by the outermost dark circular line. Similarly each of the figures 56 to 61 represents two maturing spermatids in side view, which have not separated. Warren derives the swollen nuclei, which are really spermatogonial nuclei (figs. 52 and 53), directly from the small, oval nuclei of the young lobe, but we must reject the account of amitosis of these vesicular nuclei as given by him (figs. 32 to 34).

3. *Large-celled Glandular Lobe.*—The cells forming these lobes are of considerable size, with large nuclei rich in chromatin. Cell-outlines are conspicuously present. 'Subsequently the chromatin of the large nuclei breaks up into a cluster of rounded chromosomes, and the nuclear membrane disappears (text-fig. 3, *g*). These cells may then undergo mitotic division, but the cells thus formed are still of considerable size and the chromatin passes into an amorphous condition (Pl. XVIII, fig. 29). At the same time, the cytoplasm becomes impoverished, and ultimately it mostly disappears, and there remains a skeletal network of cell membranes with each compartment containing a ragged lump of deeply staining chromatin which represents the degenerated nucleus (text-fig. 3, *J*).'—(p. 365). Warren assumes 'that the lobe has a secretory function, and possibly it produces a hormone. Most certainly it never forms spermatozoa of any kind.'—(p. 365).

We have no doubt that the large cells described by Warren in these lobes are the primary spermatocytes and the mitotic divisions described by him are the first meiotic divisions. Probably he has mixed up the second meiotic divisions with the first, as is strongly indicated by the fact that he is really describing maturing spermatids with vacuoles developing in the cytoplasm when he talks of the cytoplasm becoming impoverished, and ultimately disappearing, there remaining a skeletal network of cell membranes with each compartment containing a ragged lump of deeply staining chromatin, which represents the degenerated nucleus.

4. *Lobe producing solitary abortive spermatozoa.*—Under this heading Warren begins correctly, but unfortunately ends wrongly. He begins with a description of the large-celled lobes (Pl. XIX, figs. 36 to 38). These figures undoubtedly represent primary spermatocytes undergoing mitosis. Warren says that these cells undergo two mitotic divisions (which means that he has seen both the meiotic divisions), and the small cells thus formed are doubtless to be regarded as spermatids. The chromosomes of the spermatids form a small nucleus with nuclear membrane. The nucleus passes to the periphery of the spermatid (Pl. XIX, fig. 43). The cytoplasm of the spermatid practically disappears, and there is left a mere hollow vesicle to which the transformed nucleus is fused (Pl. XIX, figs. 35, 49, *a.sp.*; text-fig. 3, *i*). At last Warren describes correctly the cytoplasmic vesicle of the maturing spermatid as a hollow vesicle, and not erroneously as 'homogeneous nucleus' (vide *supra*). So far Warren's account is correct. But he erroneously assumes that 'active absorption clearly occurs in such lobes, and the nuclei, which are apparently quite incapable of separating from the vesicles as functional spermatozoa, degenerate.'—(p. 366). It is not known why Warren, having given a more or less correct account of the genesis of the sperm, should suddenly arrive at the conclusion that these spermatids, really maturing in a perfectly normal way, degenerate.

5. *Small-Celled Glandular Lobes.*—According to Warren, 'the spermatids produced by mitotic divisions in a large-celled lobe (text-fig. 3, *H*) may be converted into a mass of very small cells; and such a lobe is undoubtedly an accessory genital gland (Pl. XIX, figs. 39, 40, 42, *gl.t*; text-fig. 3, *k*).' A comparison of Warren's figures with ours clearly shows that Warren is describing the earliest spermatids; but his conclusion that such a lobe is an accessory genital gland is wholly unwarranted.

6. *Reticular Lobes.*—'These lobes are situated in the more posterior part of the series. The young club-shaped lobe develops into a lobulated structure with permanent wide canals (text-fig. 3, *d*). The walls of these canals consist of a plasmodium with rounded, granular nuclei (Pl. XVIII, fig. 18, *gl.n.*). Mitotic division can be found taking place among the nuclei (figs. 17, 18).'—(p. 366). According to Warren these rounded granular nuclei are undoubtedly secretory in function. This again is a wholly unwarranted conclusion. A comparison of Warren's fig. 18 with our figs. 1 to 4, Plate I, will clearly show that in fig. 18 Warren is really dealing with a lobe containing resting and dividing spermatogonia whose nuclei show one large nucleolus, which is definitely more prominent than the other granules found in the nuclei. Some of the spermatogonial cells in fig. 18 are dividing, showing metaphases and telophases. Scattered amongst the spermatogonial cells are a few minute, bilateral spermatozoa which Warren erroneously considers as non-functional.

Warren concludes in the case of *Odontopyge* sp.—(1) that abundant sperm is produced in a simple, direct manner in the walls of the reticulum, where no mitosis has been observed, and (2) that although in certain lateral lobes mitosis is prevalent and typical spermatids may be formed, yet these lobes are mostly converted into glandular tissues and produce very few, if any, functional spermatozoa. As shown above these conclusions of

Warren are wholly unwarranted as they are based on grossly inaccurate interpretations of faulty preparations. Warren used alcoholic Bouin as a fixative and in many cases he fixed the entire animal without dissecting out the testes.

In *Poratophilus diplodontus* Warren describes bilateral spermatozoa which, according to him, are produced in the vasa deferentia (figs. 65, 69 and 70, Pl. XIX). The so-called bilateral spermatozoa are really two spermatozoa arising from two sister spermatids, which have not separated; and Warren again erroneously describes them as having originated in the vasa deferentia. He also describes unilateral, abortive or degenerate spermatozoa, arising singly or in pairs from 'the homogeneous swollen nuclei', which, as in *Odontopyge*, are really the cytoplasmic vesicles (figs. 71 and 72, Pl. XIX) of maturing spermatids.

In *Chersastus ruber* Warren describes unilateral spermatozoa in the ladder-system (vasa deferentia and their transverse bridges), which he again erroneously derives from the walls of the tubes. The spermatozoa are shallow saucers in shape (fig. 95), which Warren compares to the unilateral sperm or to half of a bilateral sperm of *Odontopyge* or *Poratophilus*. They arise more usually in a single condition. As in *Odontopyge* and *Poratophilus* they are erroneously described having arisen from the so-called 'homogeneous nuclei', which are indeed the cytoplasmic vesicles of maturing spermatids (figs. 89 to 92). Pairs of unilateral spermatozoa are sometimes produced (figs. 93 to 95).

Warren again quite arbitrarily divides the spermatic lobes in *Chersastus ruber* into four classes:—(1) hollow lobes with thick walls producing sperm mostly in pairs, (2) lobes with moderately thick walls producing sperm mostly in groups of 2 to 6, (3) large-celled glandular lobes with extremely thin walls, and (4) lobes producing abortive sperm. It is easy to show, as we have shown in the case of *Odontopyge* sp., that the lobes are really all alike, but they simply contain sperm-forming cells in different stages of development.

The hollow lobe in the young condition increases in size by the multiplication of the undifferentiated nuclei through fission. These nuclei are situated as a layer surrounding the incipient lumen, and they may become conspicuously elongated before splitting transversely (Pl. XX, fig. 99). The outer nuclei thus formed become transformed into 'rosette-nuclei'. Ultimately all the undifferentiated nuclei in the body of the lobe are converted into rosette-nuclei. The thick wall of the body of the lobe bears mostly rosette-nuclei (Pl. XX, fig. 96). 'Some of the nuclei situated more internally swell and the chromatin dissolves, and there is formed a homogeneous, globular nucleus (*h.n.*). Subsequently, on opposite sides, two saucers of faintly staining chromatin are condensed around plasmosomes (fig. 98). The spermatozoa pass into the wide cavity of the lobe, and they may remain for some time coupled together in pairs (figs. 96, 97). The members of the pairs (*S.bi*), however, are only loosely applied to each other and readily separate (fig. 98). It would appear that a good many of the homogeneous swollen nuclei often fail to form the chromatin plates,

and they remain in the tissue as residual globules of large size.'—(pp. 372 to 374).

It is clear that once more Warren has made a serious error in mistaking cytoplasmic vesicles of sperms seen from front for the so-called homogeneous nuclei. Warren is rightly puzzled to have seen that a good many of the 'homogeneous swollen nuclei' often fail to form the 'chromatin plates', because the last-named structures, which are really the nuclear cups, cannot be seen except in the side view of the sperm.

Warren's figures of amitosis (Pl. XX, fig. 99) are unconvincing and his so-called 'rosette-nuclei' are possibly the nuclei of primary spermatocytes in prophase.

Warren's statement that 'these lobes, for some unknown reason, are not very satisfactory sources of production for functional sperm' is wholly unwarranted.

In the second type of lobe described in *Chersastus* by Warren (that is, lobes with moderately thick walls) he has described a peculiar phenomenon which clearly needs re-investigation. 'As the young lobe grows, the inner rosette-nuclei expand and become homogeneous, and the cavity of the lobe may become almost wholly occupied with the developing groups of spermatozoa (Pl. XX, figs. 101 to 106); the outer nuclei remain unchanged in a fairly thick, presistent wall (text-fig. 4, *c*). The expanded homogeneous nuclei (fig. 103, *h.n.*) give rise to a variable number of spermatozoa; some seem to produce none at all, the remainder form from one to six. The spermatozoa arise peripherally, the chromatin gradually condensing around plasmosome as faintly staining saucer-shaped structures. *The commonest number produced is four* (italics ours), but there are many 3's, also 2's and 1's. Less frequently 5 or even 6 can be counted.'

Strangely enough Warren rejects the only reasonable explanation of groups of four spermatozoa, viz., that a group of 4 spermatozoa has arisen from a primary spermatocyte which has undergone the usual two meiotic divisions without cytoplasmic cleavage. Regarding group of 3 spermatozoa it is possible that these are really groups of 4 spermatozoa but in section three spermatozoa are being seen from the side showing their respective nuclear cups, whereas the fourth sperm is being seen from the front (see Warren's fig. 103). Groups of 2 spermatozoa will obviously arise from 2 spermatids which have failed to separate; and a single sperm offers no difficulty whatsoever. Lastly Warren's account of the genesis of a sperm from the 'homogeneous nucleus' is so fantastic that no reliance can be placed on his statement that there are groups of 5 and 6 spermatozoa. It may be noted that the so-called 'rosette-nuclei' shown in figs. 101 and 103 are probably those of primary spermatocytes in prophase.

The large-celled glandular lobes of *Chersastus* have large nuclei with abundant floccular chromatin and surrounded by well-marked specialized cytoplasm (Pl. XX, figs. 115 and 116). A look at these figures will convince anybody that these nuclei are those of primary spermatocytes in or approaching the synizesis stage, the chromatin having already formed a knot in a few cases. Yet, for some unknown reason, Warren erroneously believes that these nuclei persist without further change and further supposes

that the tissue produces some substance which passes down the hollow stalk into the vas deferens, or is absorbed in the blood. It may be noted that these so-called glandular lobes actually contain spermatozoa in their lumen.

Lastly Warren describes lobes producing abortive sperm in *Chersastus*. He has described similar lobes in *Odontopyge* (vide *supra*). In these lobes he correctly describes the formation of spermatids from the primary spermatocytes by two mitotic divisions (Pl. XX, figs. 114, 117 and 118), but, for some unknown reason, he considers the spermatids maturing in a perfectly normal fashion as abortive.

In *Ulodesmus bispinosus* Warren describes the vasa deferentia as wide tubes extending backwards nearly straight. These tubes are connected by transverse tubes, forming a ladder-system. The lumen of the system contains a dense mass of very minute sperms which, according to Warren, are formed in the walls of the vasa deferentia. The spermatozoa have a diameter of about $0{\cdot}7\mu$ which is only about three times the diameter of the virus particle ($0{\cdot}23\mu$) of vaccinia. In support of this statement Warren puts forth the most astounding argument that because 'there seemed to be more sperm in the ladder-system than could be easily accounted for by the partially emptied lobes, it is quite likely that at an earlier stage the walls themselves had produced sperm.'—(p. 378).

The lateral lobes of *Ulodesmus* include both spermatic and glandular lobes. As the material was sparse and young specimens were not available, Warren says that he has not been able to give the full developmental history of these lobes. He has not observed mitotic figures in any part of the genital system of this species, but he has seen binary fission.

The account of the origin of spermatozoa in this species is perhaps more fantastic than that given for other species; and it is impossible to accept it. 'The nuclei of the concentric layers swell so that they come into mutual contact. The chromatin at first is irregularly dispersed in the form of granules and delicate branching strands (figs. 128, 130, 132 and 136, *p. sp.*), and there is a small rounded karyosome.'—(p. 379). Warren regards these nuclei as those of primary spermatocytes but, since these nuclei show the characteristic karyosome, they are probably those of the spermatogonia.

Warren continues: 'On expansion occurring the chromatin concentrates into a number of rounded or oval bodies which pass to the periphery of the nucleus (figs. 127, 137, *sp.*); the karyosome generally disappears entirely. In this millipede the nuclei do not pass into a homogeneous condition with the temporary disappearance of the chromatin, as in the previous species, but there is the gradual production of the above-mentioned minute bodies by the concentration of chromatin granules which are strongly basophil. These bodies are directly transformed into exceptionally small spermatozoa, and, so far as it is possible to ascertain, each nucleus may produce a dozen or more of such sperms.'—(pp. 380 to 381).

Warren anticipates that this account is bound to be received with scepticism by the genetic cytologist whom, however, he invites to inspect the drawings of the sections, and to endeavour to fit them into the typical scheme of spermatogenesis. We suspect that the nuclei described above

by Warren as having a number of rounded or oval bodies which are said to form the very minute spermatozoa are those of primary spermatocytes in the stage known as diakinesis, common in Prophase I, in which the chromosomes are arranged just under the nuclear membrane.

The so-called glandular lobes of *Ulodesmus* with small nuclei (Warren's figs. 138 and 139) are most certainly lobes which are full of the earliest spermatids and he erroneously considers them as glandular in function as in the case of the small-celled glandular lobes of *Odontopyge* (vide *supra*).

Sphaerotherium punctulatum is the last millipede described by Warren. In this millipede 'there is very little evidence that the walls of the vasa deferentia produce spermatozoa', although Warren has not produced any evidence whatsoever in favour of his claim that the spermatozoa found in the vasa deferentia of *Odontopyge* sp., *Poratophilus diplodontus*, *Chersastus ruber* and *Ulodesmus bispinosus* originate *in situ*.

While Warren derives the sperm from what he calls the 'homogeneous nucleus', which is really the cytoplasmic vesicle of a maturing spermatid, in *Odontopyge*, *Poratophilus* and *Chersastus*, and from chromosomes of the nuclei of primary spermatocytes in diakinesis in *Ulodesmus*, here in *sphaerotherium* he derives the entire sperm from an undifferentiated nucleus which becomes homogeneous.

'The spermatozoa arise in a central cluster continuous with the incipient lumen which is developed (text-fig. 6, *b*; Pl. XXII, fig. 149). The spermatozoa are not formed from the large cells which enclose the cluster, but they originate by a transformation of the undifferentiated small nuclei which must be regarded as potential sex nuclei (Pl. XXII, fig. 151, *u.n.*, *h.n.*, *sp.*).'—(p. 385). Because the undifferentiated nuclei are found immediately around the growing cluster of spermatozoa and because they also occur around the incipient lumen and extend into the embedded stalk of the spermatic lobe, Warren jumps to the conclusion that the sperms must arise from these nuclei.

The fact is that in *Thyroglutus malayus* the nurse-cell nuclei of the walls of the spermatic lobes often project into the interior of the lobes. The same phenomenon has been observed by Nath (1942) in the spermatogenesis of the Decapoda. Indeed this is a very wide-spread phenomenon and Warren has produced no evidence whatsoever in favour of his claim that these 'undifferentiated nuclei' directly form the spermatozoa.

Warren continues: 'As the cluster extends the large cells (Pl. XXII, fig. 150, *gl.n.*) with their nuclei break down, and doubtless thereby yield nutritive substances to the growing mass of sperm.'—(p. 385). This is a wholly unwarranted statement for which no evidence whatsoever has been produced by Warren. As a matter of fact the large nuclei shown in Pl. XXII, figs. 149 to 151 are perfectly healthy nuclei and are certainly those of the primary spermatocytes in or approaching the synizesis stage in Prophase I.

The spermatozoa of *Sphaerotherium* are unilateral in character and arise by the direct transformation of the undifferentiated small nuclei. In general form they are similar to those of other species, but on the concave side of the nuclear cup Warren has described 'a small conical projection

over the site of the plasmosome' (text-fig. 7, *é*). The 'plasmosome' is, of course, the centrosome, which appears to be elongated and running through the cytoplasmic vesicle of the sperm, thus forming 'a small, conical projection over the site of the plasmosome'. Gilson (1886) has figured a similarly situated rod-like structure in the sperm of *Julus sabulosus*, which is probably the centrosome.

In addition to the spermatic lobes Warren has described glandular lobes in *sphaerotherium*. The cells forming these lobes are small and Warren correctly regards these cells as spermatids. He has also figured somewhat smaller spermatozoa in these lobes, but he considers these spermatozoa as abortive. 'The small-celled tissue with the abortive sperm ultimately breaks down, and it is suggested that it produces nutritive or stimulating substances for the growth and maintenance of the functional spermatozoa formed in the spermatic lobes.'—(p. 387). No evidence has been produced by Warren in support of this view.

Oettinger (1909), working on *Pachyiulus varius*, confines himself mainly to chromosomes, but it is impossible to follow him through the process of spermateleosis in spite of the excellent figures he has produced as his homologies are mostly wrong and the fixatives used (Hermann's and Flemming's Osmium mixtures) contain acetic acid. Oettinger has described a very unusual structure in the sperm of *Pachyiulus varius*, viz., a tail filament, which, however, is conspicuous by its absence in the sperms of *Thyroglutus malayus* described by us, of *Glomeris marginata*, *Polydesmus complanatus* and three species of *Julus* (Gilson, 1886), and of *Odontopyge* sp., *Poratophilus diplodontus*, *Chersastus ruber*, *Ulodesmus bispinosus*, and *Sphaerotherium punctulatum* (Warren, 1934).

But it is not easy to dismiss the tail filament of *Pachyiulus* as an artifact, because Oettinger has figured it in the living spermatozoa and he lays particular stress on the extraordinary distinctness of this structure. Oettinger also claims to have demonstrated this structure on the occasion of a lecture held in Marburg in the Society for furthering the science of living spermatozoa. With the progress of the transformation of the spermatid the flagellum grows on to a relatively long fibre, which, in its final form, amounts to approximately three times the size of the whole cell. Oettinger is not certain whether the flagellum is capable of making any movement. We have repeatedly examined Oettinger's figures and script with great care in the hope of offering some constructive criticism in the light of our own observations, as we have done in the case of Warren's account, but we have failed to evolve any order out of the existing chaos. Evidently a comprehensive and intensive survey of the millipede sperm is urgently needed particularly the flagellate sperm of *Pachyiulus* and the filiform sperm of *Blaniulus guttulatus* (Gilson, 1886).

Summary and Conclusions

1. In this paper the spermatogenesis of *Thyroglutus malayus* has been completely worked out.

2. In the earliest spermatogonia, the nucleus hardly reveals any structure save for the presence of an excentric nucleolus, which seems to

be of the nature of an amphinucleolus. The mitochondria exist as pale fine granules in the cytoplasm arranged in the form of a juxta-nuclear mass and the Golgi elements, in the form of darkly staining bigger granules, are scattered amongst them. In the fully grown spermatogonia both the mitochondria and the Golgi elements become circum-nuclear in arrangement.

3. The primary spermatocytes are definitely larger cells than the spermatogonia. The nucleolus seems to break up into a large number of deeply staining chromatin granules. The resting secondary spermatocytes are similar to the primary but they are definitely smaller than the latter.

4. During the spermatogonial and the meiotic divisions the mitochondria and the Golgi elements are seen to be sorted out, more or less equally, to the daughter cells.

5. Beautiful spindles appear during the above stated divisions. These are fibrillar and fusiform structures with a sharply staining centrosome at each pole.

6. The earliest spermatid has, beside a nucleus, a few prominent Golgi elements, a large centrosome and fine granular mitochondria.

7. During spermateleosis the vesicular nucleus of the early spermatid is converted into a wide and shallow cup. Simultaneously vacuoles appear in the cytoplasm and both the mitochondria and the Golgi elements merge into these. By a two-fold process of growth and coalescence these vacuoles form a large cytoplasmic vesicle, which is pushed inside the nuclear cup just before the ripe sperm is formed.

8. The ripe sperm is a simple structure consisting of three cell-elements only, viz., the nuclear cup, the centrosome and the cytoplasmic vesicle. The acrosome, the middle-piece and the axial filament of the typical flagellate sperm are conspicuous by their absence.

9. The structure of the centrosomal apparatus has been studied in detail and its large size is supposed to be in conformity with the belief that it is in some way connected with the opening out of the sperm.

10. Since the ripe sperm is completely devoid of an acrosome, this investigation tends to disprove its alleged boring function.

Explanation of Figures in the Plates

All figures have been drawn with a camera lucida at the table level with Beck 25 MM(×10) eye-piece and oil immersion objective giving a magnification of 1,700 times.

All figures except figs. 50 to 53 on Plate IV have been drawn from sectioned material fixed in Flemming, without acetic, followed by 0·5% iron-haematoxylin. Figures 50 to 53 are from smears fixed in Flemming, without acetic, diluted with an equal quantity of water and stained with 0·5% iron-haematoxylin.

CONSTITUTION OF PERIODATE OF URANIUM.

By Balwant Singh, Apar Singh *and* Roshan Singh.

C. F. Rammelsberg (*Pogg. Ann.*, 1839, 55, 70) found that when uranium tetra-chloride is treated with potassium periodate, a greyish green precipitate of uranous periodate is formed, which soon passes into yellowish white uranyl periodate.

In the present investigation, an attempt has been made to prepare periodate of uranium and to determine its constitution.

Experimental.

On adding potassium meta-periodate solution to a warm saturated aqueous solution of uranyl nitrate, a yellowish white precipitate was formed. It was filtered, washed with hot water till free from nitrate, dried in an electric air oven at 60° C. and analyzed. Uranium content of the periodate was determined by Oxine method (Vogel, *Quantitative Inorganic Analysis*, 1948, page 557). Iodine and available oxygen in the compound were estimated by Kimmins' method modified by Bahl and Partington (*J. Chem. Soc.*, 1934, page 1087). The analytical results are given in the following tables:

Table I—*Uranium.*

Sample No.	Periodate taken. (gm.)	Oxine Compound of Uranium. (gm.)	Percentage of Uranium in Periodate.
1	0·1901	0·3311	58·96

	0·1982	14·17	10·21
			Mean value 10·28

DISCUSSION.

On adding potassium meta-periodate solution to a warm saturated aqueous solution of uranyl nitrate, a yellowish white precipitate of $UO_2(IO_4)_2 . 2\ UO_3$ is formed according to the following reactions:

$$UO_2(NO_3)_2 + 2\ KIO_4 = UO_2(IO_4)_2 + 2\ KNO_3.$$
$$UO_2(NO_3)_2 + 2\ H_2O \rightleftarrows H_2UO_4 + 2\ HNO_3.$$
$$2\ H_2UO_4 = 2\ UO_3 + 2\ H_2O.$$
$$UO_2(IO_4)_2 + 2\ UO_3 = UO_2(IO_4)_2 . 2\ UO_3.$$

On heating the compound decomposes to give

$$UO_2(IO_4)_2 . 2\ UO_3 = UO_2 + 2\ UO_3 + I_2 + 4\ O_2.$$

10·46 per cent of available oxygen. Calculated values of uranium and iodine in this compound are 58·35 per cent and 20·74 per cent respectively.

The analytical and the calculated values of uranium, iodine and available oxygen in the periodate of uranium agree with its formula $UO_2(IO_4)_2 . 2\ UO_3$.

ALKALINE PERMANGANATE AS A VOLUMETRIC REAGENT (PART I)

Estimation of Organic Hydroxy Acids

by

RAM CHAND PAUL, V. S. GAIND, O. P. MALHOTRA and RAJKUMARI NAHAN (MISS)

(Department of Chemistry, Panjab University College, Hoshiarpur)

ALKALINE PERMANGANATE AS A VOLUMETRIC REAGENT (PART I).

Estimation of Organic Hydroxy Acids.

By Ram Chand Paul, V. S. Gaind, O. P. Malhotra *and* Rajkumari Nahan (Miss).

Holluta (1922) has shown that the reaction between potassium permanganate and a formate in alkaline solutions proceeds in two distinct stages:—

(i) The reduction of permanganate to manganate

$$MnO_4^- + e^- \longrightarrow MnO_4^{--} \quad .. \quad .. \quad (1)$$

and (ii) The reduction of manganate to manganite

$$MnO_4^{--} \longrightarrow MnO_3^{--} + O \quad .. \quad .. \quad (2)$$

The first of these two reactions proceeds much more rapidly than the second one, which is in conformity with the findings of Sackur and Taegener (1912) who determined the normal potentials of the reactions (1) and (2) to be +0·61 and +0·50 volt (at about 18° C. and 1 *N* KOH solution). Stamm (1934) found that under the conditions in which only the first stage is involved many substances, otherwise difficult to attack, can be quantitatively oxidized at room temperature in a few minutes.

The second stage of the reaction can be written as

$$MnO_4^{--} + 3H_2O + 2\,e^- \rightleftarrows H_2MnO_3 + 4OH^- \quad .. \quad (3)$$

This reaction can be hindered by increasing the hydroxyl ion concentration, because an increase in the (OH)' concentration will shift the equilibrium towards left (1·2 *N* alkaline solution can satisfy the above condition). The effect of this increase of the OH^- ion-concentration upon the reaction (1) is to shift the equilibrium to the right, i.e. to help the reaction:—

$$MnO_4^- + OH^- \longrightarrow MnO_4^{--} + OH \quad .. \quad .. \quad (4)$$

This shows that by keeping the solution strongly alkaline the first stage (1) is facilitated while the second stage (2) is checked, thus creating strong oxidizing conditions (Stamm, *loc. cit.*). The free hydroxyl which appears on the right-hand side of equation (4) is much more mobile than permanganate and manganate ions and may be the real oxidizing agent.

Thus the principle of procedure for titration in strongly alkaline medium should be such as to involve only the first rapid stage, i.e. the reduction of permanganate to manganate while the second stage involving the conversion of manganate to manganite should not be allowed to occur. This is achieved by the addition of some barium salt solution which causes the precipitation of sparingly soluble barium manganate and thus removes

the manganate ions from the reaction mixture, while the permanganate ions are still there because barium permanganate is quite soluble, in conformity with the Weitz and Stamm (1928) rule. The solubility product of barium manganate has been found by Schlesinger and Seims (1924) at 25° C. to be $2{\cdot}46 \times 10^{-10}$, which is less than that of even barium carbonate. This shows that by the addition of an excess of barium chloride solution the manganate ions can be completely removed from any further action of the reducing agent; in fact the removal is so complete that in the absence of permanganate ions or any other coloured material the supernatant solution is colourless. The precipitate of barium manganate is dark green but with practice the colour of supernatant solution can be judged easily. *Alternatively the solution can be made acidic when the oxidation is complete* and $KMnO_4$ left unreacted titrated against oxalic acid.

Keeping the above principles in view attempt here has been made to estimate certain oxidizable compounds. In this communication the estimation of certain organic hydroxy acids has been dealt with. The results about other classes of compounds will be reported shortly.

Procedure.

20 c.c. of 0·5 *N* $KMnO_4$, about 10 c.c. of 30% NaOH and 7–15 c.c. (a known volume) of approximately 0·1 *N* solution of the acid to be estimated were measured together in a 250 c.c. flask and allowed to stand for 10 to 15 minutes. The excess of permanganate is estimated by any one of the following two methods.

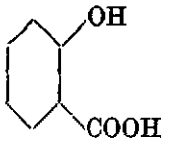
Method A:—About 15 c.c. of 30% barium chloride solution were then added and the contents diluted with water to approximately 100 c.c. The excess permanganate was then back titrated against a standard formate solution in the alkaline medium, end point being the disappearance of the colour of permanganate from the supernatant solution.

Method B:—After allowing the oxidation to complete as above the solution was acidified with 10 c.c. of dilute sulphuric acid (1 : 1) and then 20 c.c. of 0·5 *N* oxalic acid solution were added. The contents were warmed to 60–70° C. and the excess oxalic acid determined by titration against a standard (0·1–0·2 *N*) $KMnO_4$ in acidic medium.

The acids estimated by this procedure were salicylic acid, mandelic acid, lactic acid, citric acid, glycollic acid, tartaric acid and malic acid. The results are tabulated in Tables I and II.

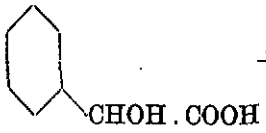
Discussion of Results.

The oxidation products in most of the cases are carbon dioxide and water, excepting in the case of mandelic acid which gives benzoic acid, which is stable in alkaline as well as acidic medium, and tartaric acid in which case in the alkaline medium the reaction ceases at the oxalic acid stage, but when the medium is made acidic for *Method B*, the oxidation proceeds to completion yielding carbon dioxide and water. The reactions may be represented as:—



$+14\,O \longrightarrow 7\,CO_2+3\,H_2O$

(Salicylic Acid)



$+2\,O \longrightarrow$  $+CO_2+H_2O$

(Mandelic Acid)

$CH_3.CHOH.COOH + 6\,O \longrightarrow 3\,CO_2+3\,H_2O$

(Lactic Acid)

$CH_2.COOH$
$C(OH).COOH \quad +9\,O \longrightarrow 6\,CO_2+4\,H_2O$
$CH_2.COOH$

(Citric Acid)

CH_2OH
$+3\,O \longrightarrow 2\,CO_2+2\,H_2O$
$COOH$

(Glycollic Acid)

$CHOH.COOH$
$+4\,O \xrightarrow[\text{Medium}]{\text{Alkaline}} COOH \quad +2\,CO_2+2\,H_2O$
$CHOH.COOH \qquad\qquad COOH$

(Tartaric Acid)

$CHOH.COOH$
$+5\,O \xrightarrow[\text{Medium}]{\text{Acidic}} 4\,CO_2+3H_2O$
$CHOH.COOH$

(Tartaric Acid)

$CH_2.COOH$
$+6\,O \longrightarrow 4\,CO_2+3\,H_2O$
$CHOH.COOH$

(Malic Acid)

In all the cases the best results are obtained when 80–120% excess of $KMnO_4$, over the theoretically required amount is used. Both the methods yield comparable results except in the case of citric acid when Method B gives better results than Method A.

It may be added that Method B is more convenient.

SUMMARY.

Certain aromatic and aliphatic hydroxy acids have been estimated volumetrically by using potassium permanganate in the alkaline medium using two different methods. In most of the cases acidic permanganate does not yield quantitative results.

THE EXTERNAL MORPHOLOGY OF *DIPRION PINI* (L)*

(Symphyta-Hymenoptera)

By G. L. Arora, M.Sc., D.I.C., Ph.D. (Lond.), F.R.E.S.

The literature on the external morphology of the sawflies has been accumulating for the last half a century. Van Dine (1905) described and illustrated the mouth parts of a few sawflies ; Snodgrass (1910) gave a detailed account of the thorax of *Tremex* and some other Hymenoptera; Crampton (1919) treated the male genitalia in detail; Bird (1926) dealt with the external anatomy of the adult *Hoplocampa halcyon*; Ross (1936) made a thorough study of the wing venation of the Symphyta; Reeks (1937) described the external morphology of *Diprion polytomum ;* Ross (1937) made a comparative morphological survey of the Nearctic sawflies and Snodgrass (1941) gave a detailed comparative account of the male genitalia of the Hymenoptera with a section on the Chalastogastra. In addition to these, several passing references on sawfly morphology appear in text-books and in papers on anatomy and phylogeny.

The present study of *Diprion pini* is an attempt to bring out characters which have some phylogenetic interest, difficult to secure from the writings of earlier morphologists. A fair amount of well preserved material of this sawfly could be obtained from the collections in the Department of Entomology, Imperial College, London. I am indebted to Dr. O. W. Richards of the Imperial College, London, for his invaluable advice and guidance and to Mr. R. G. Davies for his general assistance. My thanks are due to Dr. Vishwa Nath for getting the paper published in the Research Bulletin of the East Panjab University.

1. The Head

(Pl. I, Figs. 1, 2)

The head is hypognathous, globular, broader than long, convex in front and almost flattened behind and bears laterally the oval, slightly bulging compound eyes. The cranium is strongly sclerotized, highly pigmented in the male, and beset with setae and pits all over. Its surface is marked by sutures and ridges which divide it into definite areas. In the middle of the dorsal surface is a raised area, the Vertex, cut off by the temporal sutures laterally and by a horizontal pigmented line ventrally. On the anterior surface and immediately below the vertex lie the three ocelli in a triangle, with a heavily pigmented area between the lateral

* Submitted as part of the thesis for the Degree of Doctor of Philosophy of London University.

ones. The epicranial suture or the Cleavage line of the larva (Snodgrass, 1947) has no counterpart in the adult but from the middle of the horizontal line mentioned above run downward two faint frontal sutures (post-frontal sutures of Ferris, 1942), one on either side of the median ocellus and stopping short there. The fate of the epicranial suture is quite variable in the insect head. In the generalized forms the frontal bifurcation may reach the epistomal suture or even the labro-clypeal suture and the area with the median ocellus in between these is termed the Frons. In the present species, because of the obliteration of the sutures, a broad continuous area, the Fronto-parietal, comes to lie below and on the sides of the vertex, bearing the ocelli, the antennae and the eyes, and extending ventrally up to the clypeus which is separated from it by the horizontal epistomal or clypeo-frontal suture; the latter is identified by the broad anterior tentorial pits at its two ends in front of the antennae which mark the posterior limits of the clypeus. The antennae lie almost in the middle of the fronto-parietal, one on each side, a little above the anterior tentorial pit. Each antenna lies in an oval antennal socket enclosed by the antennal suture and articulates with the socket by a peg-like projection from its ventromesal border. In line with the anterior tentorial pits and immediately above the antennae can be made out a pair of dark patches, the dorsal tentorial patches or 'tentorial maculae', marking the position of the coalescence of the distal ends of the dorsal tentorial arms with the cranium. Two lateral, slightly curved ridges run from the lateral ocelli to the antennae dividing the fronto-parietal into a median area with the median ocellus and two parietal areas bearing the lateral ocelli, the antennae and the eyes. The eyes are marked by the ocular sutures and each is supported by an internal, sclerotized inflected margin or shelf. Anterior to the fronto-parietal lies the transverse, more or less trapezoidal clypeus extending to the mandibular articulations on the sides. It is bounded above by the epistomal suture and separated from the terminal flap-like, semicircular labrum by the labro-clypeal suture. The ventral border of the clypeus is somewhat inflected and covers the base of the labrum, foreshadowing a condition that one finds in other sawflies like *Pamphilius* and *Megalodontes*, in which the labrum is invaginated and only its tip is seen. The labrum (Pl. I, Fig. 3) is semicircular in outline and overhangs the oral fossa anteriorly. Its free anterior border carries long bristles, two or three rows deep. This surface is continuous with the ventral or epipharyngeal surface which is beset with setae. At the junction of the labrum with the clypeus on the epipharyngeal surface and at the outer angles of the former lie a pair of small posteriorly pointed tormae, concealed by the latter. The inner surface of the clypeus is closely attached to a highly sclerotized plate, the Pharyngeal sclerite, which is bifid posteriorly and bears setae and pits.

The genae, below and behind the eyes, are reduced due to the ventro-lateral position of the eyes. Their ventral edges bear the posterior mandibular articulations. The posterior surface of the cranium shows a vertically elongated occipital foramen in the centre with the tentorial bridge running across. A broad V-shaped area, the occiput, lies above

the foramen. It is bounded laterally by two highly pigmented sutures which are continuations of the temporal sutures mentioned before. Directed postero-ventrally below the occipital foramen is the oral fossa containing the movable mouth-parts suspended from the cranium. There are no occipital sutures and as such the limits of the genae and postgenae cannot be determined. Even a ridge (crassa) mentioned by Ross (1937) in *Tenthredo basilaris* is missing. The postgenae are, however, the broad areas on the sides of the occipital foramen, each extending from the dorsal cranial edge above to the side of the oral fossa below. The ventral edge of each postgena is weakly differentiated into an oblique ridge-like hypostoma, bounding the oral fossa laterally. The two hypostomal ridges do not meet mesally to form a hypostomal bridge but each meets the maxillaria of its side. A postoccipital suture surrounds the occipital foramen dorsally and laterally, separating the occiput and the postgenae from the narrow horse-shoe-shaped postocciput which bounds the foramen magnum. The postocciput is a narrow, pigmented sclerotized ridge continuous dorsally with the neck membrane and broadening out laterally a little above the tentorial bridge to form the occipital condyles for the articulation of the lateral cervical sclerites to be mentioned later. In front of the occipital condyles, the postocciput is continued on each side into a narrow curved pigmented sclerite, the maxillaria, affording articular surface for the maxillary cardo of its side. The maxillariae do not meet in the middle and the membranous part of the labium between them is continuous with the neck membrane. The head of *Diprion pini* is therefore of the simplest type called the 'Open Head' (Ross, 1937) characterized by the following:—

(1) The maxillariae are not fused in the middle line. They provide articulation for the cervical sclerites and the maxillary cardines.

(2) The postgenae are not produced mesally to form a postgenal bridge.

(3) The occipital foramen is continuous with the oral fossa.

(4) The anterior margin and the sides of the clypeus are free.

(5) The head capsule does not surround the mandibles at their bases. As such the oral fossa is a single one containing all the mouth-parts.

2. The Tentorium

(Pl. II, Fig. 3)

The tentorium is a well-developed, H-shaped, sclerotized structure indistinguishably fused with the pigmented sclerotized ridge which bounds the occipital foramen. It consists of three pairs of arms, the posterior, the anterior and the dorsal. The posterior arms, which are closely associated with the pigmented ridge, run inward in front of the occipital condyles to meet in the middle forming the tentorial bridge (body of tentorium) across the occipital foramen with the posterior tentorial pits at the two ends of the bridge. The anterior tentorial pits lie at the ends

of the epistomal suture a little in front of the antennae. These invaginations lead to the broad anterior tentorial arms which run upward and backward to meet the anterior margin of the tentorial bridge. The proximal half of each is fused with the maxillaria of its side and the inner margin is produced into a process. The dorsal tentorial arms originate from the outer borders of the anterior arms, each broad proximally and narrowing distally to fuse with the inner wall of the cranium at the dorsal tentorial macula.

3. The Appendages of the Head

The appendages of the head are the antennae and the mouth-parts.

A. *The Antennae*—(Pl. I, Fig. 1; Pl. II, Figs. 1, 2, 4)

The antennae show a sexual dimorphism. They are strongly pectinate in the male, consisting of 28 segments. The scape articulates with the antennal socket, there being, according to Ferris (1942) no such thing as an antennal sclerite. It is broader than long. The Pedicel is small and broad with a sensory girdle (Johnston's organ) running round its distal end. The flagellum is 26-segmented, the segments being broader than long in the proximal half and longer than broad in the distal half. All the segments bear small spines and pubescence. The basal twenty-three segments of the flagellum carry long, narrow paired prolongations, beset with spines all round whereas the last three are without *such prolongations. The paired prolongations on the proximal segments* are long, becoming smaller gradually towards the distal end of the antennae. The antennae are serrate in the female, the flagellar segments being produced into small blunt inner processes. Each antenna has twenty-four segments. The scape is large and is longer than broad. The pedicel is bulb-like with the Johnston's organ as in the male. The flagellar segments are broader than long, becoming narrow distally. They bear spinules and hair. The terminal segment carries in addition, four sense papillae near its tip.

B. *The Mouth Appendages*

The mouth-appendages include the mandibles and the maxillo-labia complex.

(*a*) *The Mandibles*—(Pl. I, Figs. 1, 2, 4)

The mandibles are triangular, highly sclerotized paired jaws, each bound to the head by a membrane round its base and articulating by an anterior ginglymus and a posterior condyle with the ventral genopostgenal border below the eye. The ginglymus is a basal anterior concavity of the mandible into which fits a knob on the side of the clypeus and the condyle is the posterior convexity at its base which fits into a socket on the lower edge of the postgena. The inner border of each mandible has a pronounced incisor area with three well-developed teeth, the distal one being the longest

and the other two progressively smaller. The mandibles are asymmetrical, lying crossed below the labrum, the left one having its distal tooth longer than that of the right and bent inward. No molar area is differentiated. A tuft of bristles is borne on the outer edge of the mandible near its middle.

(*b*) *The Maxillo-Labial Complex*—(Pl. I, Fig. 2)

The two maxillae and the labium unite to form this composite structure contained in the oral fossa and suspended from the maxillariae by the maxillary cardines, the basal membranous part of the labium (postmentum) between them being continuous with the neck membrane.

(i) *The Maxillae*—(Pl. I, Fig. 2; Pl. II, Fig. 5)

The maxillae are the lateral structures in the complex, each consisting of the proximal cardo and the distal stipes, the latter bearing two terminal lobes, the outer galea and the inner lacinia, and a lateral segmented maxillary palp. The maxillae are united to the labium by a narrow strip of membrane on either side of the latter between the inner margins of the cardo and stipes on one hand and the outer margin of the postmentum on the other; the prementum of the labium does not take part in the union. The cardo and the stipes lie postero-lateral to the labium while the galea and the lacinia come to occupy a position a little anterior to the prementum and the paraglossae. The cardo is more or less triangular, sclerotized and produced proximally into a process for articulation with the maxillaria of its side. It is produced mesally into a blunt angle which reaches as far as the median sclerite of the postmentum. Distally the cardo articulates with the stipes. The stipes is elongate and sclerotized, and bears a few bristles. It does not show any division. The galea is a globular lobe bearing setae with a special set of strong setae along its distal margin. The lacinia is a narrow, soft blade-like lobe pressed against the galea and beset with setae and pubescence on its inner surface. The maxillary palp is six-segmented with a small palpifer at its base. It is fairly long with its segments sclerotized and bearing setae and pubescence; the last segment is narrow and the longest.

(ii) *The Labium*—(Pl. I, Fig. 2).

The labium is the median component of the maxillo-labial complex, lying between the maxillae with which it is united by lateral membranous strips. It consists of a basal part, the postmentum and a distal part, the prementum. The postmentum is a membranous rectangular piece with a small sclerotized, pear-shaped setiferous plate in the middle in between the mesally directed inner angles of the cardines. The exact homologies of this sclerite are not certain. Ross (1937), Reeks (1937) and other hymenopterists have labelled it submentum. Snodgrass (1935) compares it also to the lorum (= submentum) of higher Hymenoptera but it is not connected with the cardines. It is better to call it a postmental sclerite, for in certain sawflies such as *Megalodontes klugii* there are three such sclerites, a median and two lateral. The prementum is a sclerotized piece, faintly bifid at its distal end. Its adoral surface is beset with small spines while its oral surface has the hypopharynx

immovably united with it. It carries distally three terminal conical lobes and laterally a pair of labial palps. Of the three lobes, the side ones are the paraglossae and the middle one the alaglossa formed by the fusion of the glossae. The paraglossae and the alaglossa are adorned with spines and bristles at their distal extremities. The labial palps are four-segmented, the third broadened distally and the fourth conical. Small spines are borne on all the segments.

4. The Hypopharynx

(Pl. I, Fig. 5)

The hypopharynx is a raised sclerotized lobe intimately fused with the oral surface of the prementum at the base of the alaglossa and incapable of any free movements. Its surface bears small spines. The salivary duct can be seen opening into it. Its sides are supported by a pair of suspensorial rods, one on either side.

5. The Cervix

(Pl. I, Fig. 2; Pl. III, Figs. 2, 4)

The cervix or neck region is the membranous inter-segmental portion between the head and the prothorax which is strengthened ventrolaterally by a pair of sclerites, the cervical sclerites. The latter are broad proximally and narrow distally, their distal prolongations articulating with the occipital condyles on the sides of the occipital foramen. Each sclerite sends a small process inwards and backwards just before its articulation with the occipital condyle while its proximal broad part is fused with the pro-episternum. The suture between the two has been almost obliterated; only a faint indication of one remains, showing where fusion has taken place. These neck sclerites were regarded by Snodgrass (1910) as episterna but Crampton's (1917) and Weber's (1933) view that they are cervical sclerites which have fused with the propleura, particularly when an indication of such a fusion is noticeable, seems to be more satisfactory. The cervical sclerites bend inward but do not meet each other mesally nor do they meet the prosternum, the area between them being membranous.

6. The Thorax

The thorax is formed by three segments, the prothorax, the mesothorax and the metathorax, each bearing a pair of legs. The meso- and the metathorax are the wing bearing segments and together constitute the pterothorax.

(*a*) *The Prothorax*—(Pl. III, Figs. 1, 2, 4)

The tergum of the prothorax or the pronotum is a narrow sclerotized collar in front of the mesothorax. It expands into a broad triangular plate on either side immediately above the cervical sclerite with which it is connected by a membrane. Each lateral pronotal plate is beset with small setae and its posterior ventral angle is produced into a process which

reaches as far back as the anterior edge of the mesepisternum of its side. The pronotum, thus, is associated more closely with the mesothorax than with the propleural elements. The propleuron on either side has a distinct pleural suture which runs vertically up, is marked by a pleural ridge on the inner side, and is produced backward into an apodeme. In front of the pleural suture lies the episternum faintly marked off from the cervical sclerite and behind it lies the narrow epimeron. The ventral end of the pleural suture articulates with the coxal ridge of the first coxa on the dorsal aspect of the latter, forming the pleural articulation. The venter of the prothorax shows a T-shaped eusternum, not differentiated into the basi and furcasternal elements. At either end of the T, in the membranous part in front of each coxa, lies a small sclerite, the trochantin, bearing small setae. Snodgrass (1910) calls it the accessory precoxal plate in *Arge*. Weber (1933) recognizes a small trochantin in a number of sawflies. A similar trochantin has been observed in a number of panorpoid orders. The eusternum is bifid posteriorly, each knob-like bifurcation establishing a sternal articulation with the anterior inner angle of the coxal ridge. A similar condition exists in some other sawflies also. Weber (1933) describes it as a secondary sternal articulation in *Athalia* and Snodgrass (1910) mentions an articulating plate between prosternum and coxa of *Tremex columba*. The eusternum carries a pair of furcae on the inner surface. Behind the eusternum is the membranous spinasternum with a small spine near its posterior margin.

(*b*) *The Mesothorax*—(Pl. III, Figs. 1, 2, 4)

The mesothorax is the middle segment of the thorax, well developed and much bigger than the metathorax. It carries the fore wings. The mesotergum consists of the notum (also called the alinotum by Snodgrass, 1935) and the postnotum, the former comprising the prescutum, the scutum and the scutellum. The anterior edge of the mesonotum carries an inflected ridge on the inner side, the first phragma. The prescutum is heart-shaped, lies anteriorly in the middle, bounded by two convergent sutures (notaulices) that meet in the mid-line. A median suture divides it into two. The scutum lies behind and on the sides of the prescutum and extends backward laterally on the sides of the scutellum. It thus forms two lateral areas connected by a median bridge between the approaching ends of the prescutum and the scutellum. The lateral margins of the scutum are produced outwards to form the anterior notal wing processes in front and the posterior notal wing processes behind. A scuto-scutellar suture separates the scutum from the V-shaped scutellum. A pair of lateral sutures, the parapsidal furrows, start from the sides of the scutellum and run forward and outward, setting off two latero-posterior areas of the scutum, the parapsides or parascutellar areas of Ross (1937). The scutellum is a large V-shaped sclerite in the middle with the apex of the V directed forward. Its posterior border is somewhat thickened and is termed post-tergite by Ross (1937). It is produced laterally to become continuous with the axillary cords of the wings. The postnotum is a broad sclerotized band, notched in the middle

and lying across behind the scutellum with which it is connected by a small membrane; the latter is almost covered over by the scutellum. Laterally, the postnotum runs outward, downward and forward to reach the posterior edge of the mesepimeron on either side. The posterior border of the postnotum is produced backwards into a large bifid, heavily pigmented second phragma, extending beneath the metatergum and a part of the first abdominal tergum. The mesopleuron on either side shows externally a well-developed pleural suture which runs upward and forward, dividing it into an anterior episternum and a posterior epimeron. Ventrally the pleural suture forms a dorsal pleural articulation with the ridge of the mid-coxa and is continued into an articular wing process at the other end. The episternum is fused with the basisternum, the pleurosternal suture having disappeared. There is a triangular piece cut off from the anterodorsal portion of the episternum which has been variously named parapterum, prepectus, pre-episternum and so on and has been regarded as peculiar to the hymenoptera. This piece can safely be compared to the anepisternum of the neuroptera in which the division of the episternum into an anepisternum and katepisternum is a common feature; the former may be larger, equal to or smaller than the latter. The episternum of the taxonomists corresponds then to the katepisternum which has fused with the basisternum. The mesepimeron is divided into a horizonal, narrow dorsal portion, the anepimeron and a vertical broad ventral portion, the katepimeron. A trochantin, though weakly sclerotized, starts from the lower end of the pleural suture and below the episternum and runs along the posterior margin of the sternum between it and the coxa. It is intimately fused with the sternum, its inner end curving round to articulate with the anterior coxal ridge on its inner side, a little in front and below (above when seen from the ventral side) the sternal coxal articulation. In front of the anepisternum lies the mesothoracic spiracle in a weakly sclerotized area. Behind the epimeron at the junction of the anepimeron and the katepimeron lies the meta-thoracic spiracle. The mesosternum consists of the presternum, the basisternum, the furcasternum and the spinasternum. The presternum is a narrow strip cut off from the anterior margin of the sternum, extending on the sides up to where the lateral pronotal plates meet the episterna. The basisternum is not demarcated from the episterna as it is in some other sawflies. There is, however, a prominent median suture running in the mid-ventral line with a strong ridge on the inner side. The furcasternum is a reduced sclerite behind the basisternum in the middle. Internally it bears two well-developed furcal arms which meet in the middle and run forward as a common median ridge on the inner side of the median line of the basisternum. Posteriorly the furcasternum sends a pair of processes, one on either side of the middle line, each articulating with the coxa of its side on the latter's mesal surface. These sternal coxal articulations lie dorsal and a little posterior to the trochantinal articulations mentioned before. The spinasternum is a small membranous part between the two coxae and behind the furcasternum. It can be better seen when the legs are pulled up and apart.

(c) *The Metathorax*—(Pl. III, Figs. 1, 2, 4)

The metathorax is much smaller than the mesothorax and bears the hind wings. The metanotum lacks the prescutum. The scutum consists of two lateral parts, connected by a narrow bridge in front of the scutellum. A pair of elongated, slightly raised, membranous areas, the cenchri, are differentiated on the scutum, one on either side of the middle, along its anterior border. They are narrow towards the inner side and broaden out gradually, extending to more than half the breadth each way. The lateral margins of the scutum are produced into the anterior and the posterior wing processes as in mesoscutum. There are no parapsidal sutures but faint indications exist. The scutellum is broadly triangular and punctate with a 'post-tergite,' continuous laterally with the axillary cords. The postnotum is a narrow sclerite behind the scutellum. Its hinder edge forms a weak phragma. The metapleuron shows the prominent pleural suture. The episternum is divided into anepisternum and katepisternum, the latter fused with the basisternum. The epimeron is not completely divided into two as the dividing suture bends back and stops short in the middle. The mesopleura and the metapleura are so similar that one can safely say that the so-called prepectus in the mesopleuron is nothing else but the anepisternum. The trochantin is similar to that in the mesothorax but is considerably bigger. The coxae, as in the mesothorax, have three articulations, the pleural, the trochantinal and the sternal. The metasternum has the same parts as the mesosternum except that the spinasternum is missing. The various sternal elements are, however, comparatively small.

7. The Thoracic Appendages

The thoracic appendages include the legs and the wings.

A. *The Legs*—(Pl. III, Fig. 3; Pl. IV, Figs. 3, 5)

There are three pairs of legs, the prothoracic, the mesothoracic and the metathoracic; the hind pair is the longest. The legs lie quite approximated together on the ventral side. They are similar, each consisting of the coxa, the trochanter, the femur, the tibia and the tarsus. All the segments bear small spines.

In the prothoracic leg the coxa is conical, broad proximally and narrow distally, with a thickened marginal ridge, the basicoxite, running round its proximal end. It articulates dorsally with the ventral end of the pleural suture to form the pleural articulation and ventrally with the backwardly directed process of the furcasternum to form the sternal articulation. Distally the coxa articulates with the trochanter. The latter is small, slightly broader distally and presents a two-segmented appearance because it is closely associated with a small proximal conical piece marked off from the femur by a strong suture. The femur is cylindrical and possesses distally a membranous part on its ventral aspect. The tibia is the longest segment of the leg. It is narrow proximally and broad distally and bears at its distal end two similar, finger-shaped bluntly pointed tibial spurs,

which are of classificatory importance. The tarsus is elongate and divided into five tarsomeres. Of these the first is the longest, the second, the third and the fourth progressively smaller, and the fifth longer than the second but smaller than the first. The first four tarsal segments each bear an oval, slightly cupped tarsal pulvillus. The last tarsal segment carries a pair of claws and some other structures, together designated as the pretarsus. The claws or ungues are articulated to the distal bilobed rim, the unguifer, on the dorsal side of the last tarsal segment. Each claw is curved at its extremity and bears a small tooth at its distal one-third on the ventral side. From the notch of the unguifer arises a pear-shaped sclerite, the orbicula. Its surface is marked into small areas and bears two pairs of long setae on the distal half. Lying in the terminal part of the cavity of the last tarsal segment on the ventral side is a sclerotized, sculptured sclerite, the unguitractor plate. It is more or less bell-shaped and grooved in the middle with a conspicuous apodeme at its proximal end, running through the tarsal segments. Arising between the claws and distal to the unguitractor plate is a membranous stalked adhesive organ, the arolium. It is somewhat rounded in outline. Its stalk is supported dorsally by the orbicula and ventrally by another triangular plate, the planta. The latter lies distal to the unguitractor and bears a pair of spines. The body of the arolium is supported by a pigmented ring-like camera. On the sides of the planta and at the bases of the claws can be made out two small sclerites, the basipulvilli, also known as the auxilia.

The mesothoracic and the metathoracic legs are similar to the prothoracic legs except in the number of coxal articulations. In these the coxa has three articulations, a pleural with the pleural suture, a sternal with the sternal process and a trochantinal with the trochantin. The trochantin in the meso and metathoracic legs is a weakly sclerotized element fused with the postero-lateral margin of the sternum and articulates with the coxa, a little below and in front of the sternal articulation. It will be noticed that in close association with these articulations, one finds definite sense-areas similar to the proprioceptor organs described by Pringle (1938) in the leg of *Periplaneta*. These sense-areas may be in the form of 'hair-plates' or areas with campaniform sensillae; both types may occur simultaneously in the same leg. According to Pringle's electrophysiological study these sense-areas may be regarded as 'tension receptors.' Such areas have also been observed in other insects. In *Diprion pini* there are three such sense-areas in connection with the meso and the metathoracic legs and two with the prothoracic. Ferris and Pennibaker (1939) named the trochantinal area with setae in *Agulla* (Raphidiidae) as 'trochantinal signum' which according to them is a landmark to determine whether a trochantin is present. The hind tibia in the male possesses two unequal spurs, while those of the female are equal.

B. *The Wings and their Articulations*

There are two pairs of membranous wings, the fore-wings and the hind-wings, the former slightly longer than the latter. The two wings on

either side are held together by a few hook-like hamuli along the anterior margin of the hind wing which catch on the slightly curved posterior margin of the fore-wing. Fine pubescene is borne on the wing margins.

(*a*) *The Wing Articulations*—(Pl. IV, Fig. 4)

The wings are hinged on to the sides of the mesothorax and the metathorax by their membranous bases which are strengthened by a number of articular sclerites. The anteriormost of these in the fore-wing is a small flat piece, the humeral plate, at the anterior margin of the wing-base and in association with the costa. Behind the humeral and articulating with the anterior notal wing-process is the first axillary sclerite which sends a process to the humeral plate in front and articulates by its outer margin with the inner margin of the second axillary sclerite. The latter is irregular in shape and sends an inner long process to the post-notal wing process and an outer short process to the third axillary. The second axillary is produced anteriorly into another process which reaches the base of the common subcostal+radial vein. The third axillary sclerite is also irregular and forked anteriorly, the inner limb broader than the outer and called accessory sclerite of the third axillary by Snodgrass (1910). Its outer border is closely associated with the bases of the anal veins, whereas its posterior angle reaches the tip of the prolongation of the post-notal wing process. The fourth axillary sclerite of other insects is absent. A large, laterally elongated, weakly sclerotized median plate lies outer to and in front of the second axillary. Its anterior inner angle is confluent with the common base of the $Sc+R+M+Cu$. The posterior margin of the wing is thickened to form the axillary cord, continuous with the lateral prolongation of the scutellum. Lying above the base of the wing, inner and anterior to the humeral plate, is a sclerotized scale like plate, the tegula. It has the shape of a quadrant, beset with small spines on its dorsal surface and its outer angle produced into a point.

(*b*) *The Wings*

Several systems of nomenclature for the wings of hymenoptera have been offered but Ross's system (1936) based on their derivation from the *Sialis*-like panorpoid, has been adopted because it agrees with conclusions drawn from other characters studied.

(i) *The Fore-Wing*—(Pl. IV, Fig. 1)

The fore-wing is 8·5 mm. long and 3·4 mm. broad. There is a thickened dark patch, the pterostigma, on the anterior margin near its middle, covered with small hair. The anterior margin of the wing is straight and the number of veins is relatively small, compared with some of the sawflies. The costa runs along the anterior margin. The subcosta, radius, media and cubitus are proximally fused to form a common basal vein. This divides into two branches, an anterior $Sc+R$ and a posterior $M+Cu_1$. The subcosta separates off before the pterostigma beyond which point M meets the radius. The common $R+M$ divides into R_1 and $RS+M$, the former running along the inner and the posterior margin of the

pterostigma to the border. $RS+M$ are confluent for some distance and then they separate off, each running straight to the margin of the wing. There is one cross-vein between R_1 and RS, the second having been lost, resulting in the formation of a large cell Rl_2+Rl_3. M separates from Cu_1, runs for some distance with RS and leaves it to reach the margin unbranched. There are two cross-veins between RS and M. Cu_1, after M has separated off, runs out for some distance and then divides into Cu_{1a} and Cu_{1b}, the latter receiving the common anal vein before it reaches the border. There are two cross-veins between M and Cu_1. There is no Cu_2. There is one cross-vein between Cu_1 and $1A$ and one cross-vein between $1A$ and combined $2A$ and $3A$. $2A$ and $3A$ meet and the combined vein meets $1A$, the resulting common anal running into Cu_{1b} before the latter reaches the border. There is a small jugal lobe with spinules along its margin.

(ii) *The Hind-Wing*—(Pl. IV, Fig. 2)

The hind-wing is 6·5 mm. long and 3·4 mm. broad. The pterostigma is very much reduced. Some 9–12 hook-shaped hamuli are borne on the anterior margin near its middle and a few fine setae near the base. There is no cross-vein between R_1 and RS, so a large radial cell is formed ($R_{1\ 1+2+3}$). RS and M do not run together as they do in the fore-wing. There are two cross-veins between RS and M (same as fore-wing) but only one cross-vein between M and Cu_1 (reduction). There is one cross-vein between Cu_1 and A. The anals form one anal cell and the petiole of the cell meets $Cu\ a$. An anal lobe is present.

8. The Abdomen

(Pl. V, Figs. 1, 2).

The thorax passes into the abdomen without a constriction. The abdomen consists of ten segments. The first six segments and the last are similar in the two sexes but the 7th, 8th and 9th are modified differently for oviposition and copulation.

The first segment (Pl. III, Fig. 1) has its tergum sclerotized to form two dorso-lateral pieces, narrowing in the mid-dorsal line, with a membranous part between and behind them. The sternum is small, membranous and invaginated. The abdominal spiracles of the first pair are large and are borne on the tergum, one on either side.

Segments 2–7 (Pl. V, Fig. 2) are identical, each with a dorso-lateral band-like tergum, a similar ventrolateral sternum and a membranous strip on either side between the two. Each tergum is dorsally divided into a narrow anterior portion and a broad posterior portion, the latter bearing the paired spiracles on the sides. These spiracles are smaller than those of the first pair.

The seventh sternum in the female covers posteriorly the gonopore in the membranous infolding of the VIII sternite.

The eighth tergum in the male is slightly smaller than the preceding one and bears the last pair of spiracles laterally. The sternum is not a

continuous band ventrally but is notched in the middle to form two ventro-lateral pieces. The eighth tergum in the female is comparatively larger. The eighth sternum lies behind the seventh. It is mostly membranous but there is a small sclerotized piece, partially divided into two, lying between the bases of the first valvulae. This can possibly be the remnant of the sclerotization of the VIII sternum.

A. *The Female External Genital Apparatus*

The eighth sternum and the one following are modified to form the female external genital apparatus or the ovipositor (Pl. V, Figs. 3, 4). There are two triangular sclerites, the first valvifers, one on either side behind the eighth tergum and below the ninth tergum, articulating with the latter dorsally and with the second valvifer ventrally. These sclerites belong to the eighth segment but have shifted backward. Each valvifer (also called coxite of VIII) sends inward and backward a sclerotized pigmented ramus which is continued into a blade-like ventral valve or stylet, the first valvula (also called saw; gonapophysis of 8th) broader proximally and tapering gradually towards its distal end. Each valve has a smooth inner margin and bears on its ventral surface rows of serrations on raised ridges and is produced dorsally into a longitudinal ridge which fits into a corresponding ventral groove on the inner valve, affording a sliding movement forward and backward.

The ninth tergum in the female is narrow dorsally but broadens out laterally. Its antero-lateral margins articulate with the first valvifers whereas its postero-lateral margins partially cover the second valvifers and the third valvulae. A pair of elongate second valvifers (also called coxites of IX), one on either side, lies below the first valvifers with which they articulate. The second valvifers do not articulate with the ninth segment. Laterally each second valvifer is produced backward. From its ventromesal border is given off a ramus (similar to the one given off by the first valvifer) which connects it to the blade-like second or the inner valvula (also called saw-guide, gonapophysis of 9th), while distally it articulates with a broad, sheath-like third valvula (also called style of the 9th; gonostyle). The two inner or second valvulae are connected by membrane along their inner margins throughout their length except at their posterior extremities. They are dorsally convex and ventrally concave with a groove each for the dorsal ridge of the first valvula. The surface of the fused second valvulae is marked by faint annular ridges and the margins are produced into small processes. Distally the two valvulae are unequal in length, the right one longer and slightly broader. The connecting membrane between the second valvifers and valvulae is comparable to the ninth sternum.

The tenth tergum is a small piece forming a proctiger above the anus in both sexes. It bears laterally, near its distal margin, a pair of small more or less club-shaped appendages, the cerci (also called socii), beset with strong setae. Snodgrass (1941) calls these the pygostyles. He observed a pair of cerci on the invaginated anal lobes (XI Seg.) in the male of the ichneumonid *Megarhyssa lunator* in addition to the socii on the 10th

segment. This is a solitary example where the socii and the cerci are said to be met with in the same animal. The tenth sternum is missing.

B. *The Male External Genital Apparatus*—(Pl. V, Figs. 2, 5)

The ninth tergum in the male is reduced, covered over by the eighth, concealed from view dorsally, and appearing as two lateral pieces on the sides. The ninth sternum is the largest and forms a deeply concave subgenital plate or hypandrium, covering the male genitalia ventrally.

The genital apparatus is of the strophandrious type in which the pear-shaped, dorsoventrally flattened phallus lies loosely attached in the cocavity of the hypandrium, or the genital chamber, with its primary dorsal and ventral surfaces inverted to become the lower and the upper surfaces respectively. It consists of a two-segmented phallobase, a pair of parameres (harpes), a pair of volsellae, a pair of parapenes and the aedeagus. The basal part of the phallobase, the basal ring or the gonocardo of Crampton (1919) and the gonobase of Michener (1944), is a sclerotized ring, pointed anteriorly with an oblique anteroventral opening. It articulates with the two distal, laterally placed sclerotized pieces, the parameral plates or the gonostipites of Crampton (1919) and the gonocoxites of Michener (1944), which are connected by membrane dorsally and are closely associated ventrally with a pair of broad parapenial lobes meeting in the median line. Each parameral plate carries a more or less triangular paramere or the harpe of Crampton (1919) and the gonostylus of Michener (1944), bearing setae at its distal end. On the dorsal aspect and attached to the inner sides of the parameral plates are the two broad lobes, the volsellae, each with a bifurcate beak-shaped distal end and provided with a prominent basal apodeme, running anteriorly. The aedeagus consists of a median membranous part, which receives the ejaculatory duct, and a pair of elongated penis valves, one on each side of the medium part and lying ventral to the volsellae. The penis valves are rod-like proximally and enlarge distally, the inner margins of the distal parts being concave. Each penis valve is provided with an aedeagal apodeme, running anteriorly.

A PRELIMINARY INVESTIGATION TO STUDY THE EFFECT OF FEEDING CONCENTRATES ON THE FREQUENCY OF OESTRUS IN CATTLE

By G. P. Sharma,[1] K. N. Vali[2] *and* K. R. Suri, *Animal Genetics Section, Government Livestock Farm, Hissar*

Introduction

A common difficulty felt in this country is that sufficient number of females on heat is, as a rule, not available when work on artificial insemination is in hand. To overcome this difficulty, a small-scale experiment on 40 hill-goats was conducted at this farm in 1944-45 by Dr. J. K. Makhijani, the then Animal Geneticist, and he concluded that feeding of *methi* seed (*Trigonella foenumgroecum*) could be successfully employed for increasing the frequency of oestrus in goats.

In 1946, while adopting the Annual Report of the Scheme to Supplement Livestock Investigation, Hissar, for the year 1944-45, the Animal Breeding Committee and the Advisory Board of the Indian Council of Agricultural Research emphasized upon the necessity of further investigational work on feeding *methi* seed for bringing animals into oestrus. In response to these remarks an experiment on 40 young Hariana heifers, each about $2\frac{3}{4}$ years old, was conducted during the year 1946-47. Four groups, each of ten animals, were formed and each group was given a different treatment. The data collected for one year's experimentation revealed that the number of animals put in each group was not sufficient, as some animals under different treatments did not come on heat even once during the entire experimental period. The statistical analysis of the data was, thus, rendered difficult and no useful results of practical importance could be achieved. Fresh experimental work was, therefore, started on the 6th May, 1948.

Previous Work

From a careful study of the Literature, it appears that very little work dealing specifically with the influence of nutrition on the frequency of oestrus in farm animals has been done. Some references to the effect of feeding on early onset of oestrus, and on the length of oestrous cycle are, however, available.

Darlow and Hawkins (1933) found that breeding was more effective with ewes receiving modified rations than with ewes receiving only prairie

hay. Clark (1934) stated that flushing did not appear to have any significant influence on accelerating onset of heat in ewes and that gain in weight was not in itself indicative of higher ovulation rate. Okulicev (1934) found that flushing had good influence on lamb crops by reducing the percentage of barren ewes and raising the percentage of multiple births. It also reduced the death rate amongst the new-born lambs and the percentage of still-births. It seemed that feeding of barley was the most and that of millet the least satisfactory. Tebbe (1935) stated that a *slimming diet may induce oestrus in cows.* Polovceva *et al.* (1938) concluded that feeding of concentrates to ewes increased the number of multiple ovarian follicles and of lambs born. Addition of phosphates did not appear to affect ovarian function. Kelley (1939), working with sheep, noticed that the incidence of oestrus decreased during the spring months and increased in the summer months, the higher incidence being maintained during late summer, autumn and winter. His data, however, did not support the suggestion that the reproductive rhythm was directly associated with periodicity of the plane of nutrition. Sinicyn (1939) made observations on three groups of ewes which grazed respectively on natural steppe pasture, lucerne and winter barley aftermath, and showed that the rate of lambing was lowest in the group grazing on natural pasture. This result was ascribed to differences in chemical composition, vitamin and water content of the fodder. Ovsjannikov (1940) observed that a ration rich in proteins caused a 25% increase in fertility in pigs. Underwood and Shier (1941) found that flushing produced a highly significant increase in fertility due entirely to an increased proportion of twins. It, however, did not bring the ewes into oestrus any earlier, nor did it increase the percentage of ewes which conceived. Palmer *et al.* (1941) concluded that a combined deficiency of phosphorus and protein in the bovines, analogous to similar deficiencies in animals reared largely on prairie hay in the phosphorus deficient regions, delayed sexual maturity and repressed normal evidences of oestrum, missing thereby periods of oestrum, but did not interfere with the normal regularity of ovulation or the ease of conception. Briggs *et al.* (1942) did not observe any difference in time of first oestrus between flushed and unflushed groups of ewes. The unflushed ewes had, however, significantly longer oestrous cycles.

Material and Methods

Sixty young Hariana heifers, each of about $2\frac{3}{4}$ years in age and possessing normal conformation, were selected from the farm-bred stock at Hissar for this experiment. These animals were divided into 15 blocks, each consisting of 4 animals of as equal an age as possible. This was done to eliminate, as far as possible, the effect of age which seemed to influence the onset of oestrus to a great extent. Since the lay-out of the experiment was on a Fisherian 'Randomized Block Design', the four proposed treatments were allotted at random to the animals within each block. Thus, by separating the block differences, i.e. differences between the various age groups from the main error, a true and proper estimation of the experimental error was obtained.

The plan of feeding in the four treatments was as follows:

Treatment No. 1 .. Grazing only (Control).
Treatment No. 2 .. Grazing plus one seer of gram per head daily.
Treatment No. 3 .. Grazing plus half seer of gram and half seer of *bajra* (Pearl millet) per head daily.
Treatment No. 4 .. Grazing plus half seer of gram and half seer of *methi* seed (Fenugreek) per head daily.

It may be stated here that free grazing was preferred over stall-feeding as it was observed that the animals in the Hariana tract in general and at the Hissar Farm in particular did not thrive well if they were stall-fed. If the rains are normal the grasses in the *bir* (reserved forest) attached to the Hissar Farm grow in such abundance that the animals do not care to look at the other fodder crops. However, when grazing is not adequate roughages are also fed to all the animals. The roughages normally available at the Farm are:

1. Grasses .. Anjan (*Pennisetum chenchorides*); Dub (*Cynodon dactylon*).
2. Straws .. Oat and Wheat *bhusa*.
3. Hays .. *Jowar* and grasses.
4. Greens .. Berseem, *Jowar* and Lucerne.
5. Silage .. *Jowar* and grasses.

Bajra and *methi* seed, used as feeds in treatment No. 3 and 4 respectively, were analysed at the Animal Nutrition Section of the Indian Veterinary Research Institute, Izatnagar, and the results of analyses on dry matter basis were as follows:

	Bajra %	*Methi* %
Ether extract	2·766	7·962
Ash	2·309	4·438
Crude protein	13·369	24·797
Crude fibre	1·862	11·917
Nitrogen-free extract	79·694	50·886

Since the various signs of oestrus in an animal are displayed best when a bull or other cows are present nearby, all the experimental animals were let loose in an enclosure along with two vasectomized bulls. They were always kept under close observation and were tied only at the time of feeding. A careful record was made of the date and time when a particular animal came on and went off heat. The following description of the signs of heat in cows is from Hammond (1927):

'At the onset of heat a cow becomes restless and frequently when tied in the stall is seen standing while the others are lying down. She twitches her tail frequently and often raises it. When out at grass the cow does not usually continue to feed but wanders about the field and frequently goes off by herself or with another cow which she rides or is ridden by. She will also frequently jump the bull and when he attempts to serve her will stand still and not move away as happens when the animal is not on heat. A cow on heat also frequently lowers the hips and small of the back and raises the tail

head; she also, more especially after jumping other cows (and after service by the bull), arches her back and strains, a string of glairy mucus coming away from the vulva at this time.'

'When on heat she will also frequently play with the bull by horning him or will stand and lick him, and when separated from other cattle will low or "blar". The bull will "hang round" a cow that is just coming on or going off, although she is not actually on heat at the time, and will not stand to service.'

During the course of this investigation, which continued for full one year, it was observed that besides one heifer which calved, there were four others which did not show any signs of heat at all. While the inclusion of the already pregnant heifer in the experiment could reasonably be ascribed to the fact that her early pregnancy was not detected at the time of her selection, no satisfactory reason for the absence of oestrus in the other four animals could be given without a careful study of their future behaviour. These animals were, therefore, retained for further study, of course, under normal conditions. Out of these four animals three came on heat later and this was probably the result of their late maturity. The fourth heifer seemed to be an abnormal case inasmuch as her reproductive organs were found, on rectal and vaginal examinations, to be under-developed. A zero was, therefore, put in Table I to represent the number of heats recorded for all those animals which did not show any signs of heat throughout the experimental period but were normal. The data thus collected were as follows (dashes representing the abnormal cases):

TABLE I

Number of heats recorded

Treatments / Blocks	I (Control)	II (Gram)	III (Gram & *Bajra*)	IV (Gram & *Methi* seed)
1	1	4	11	4
2	1	9	7	13
3	2	0	10	6
4	2	3	2	—
5	4	10	11	1
6	2	—	2	4
7	3	7	9	4
8	1	2	2	2
9	8	4	9	3
10	14	1	1	5
11	3	1	3	2
12	0	6	5	6
13	0	7	4	6
14	1	2	7	3
15	1	1	9	9
TOTAL ..	43	57	92	68

STATISTICAL ANALYSIS AND THE RESULTS

Obviously the straightforward analysis of variance of the data could not be made as these were non-orthogonal. Moreover, from a look at the data, the animals in the 'control' group did not appear to behave so

consistently as those in the other groups. This might, of course, arise out of chance effects. The data, however, were examined in various ways by one of us (K. N. Vali) in consultation with the statistical section of the Indian Council of Agricultural Research. The details of the analyses and the results achieved were as follows:

1. *Study on the three treated groups leaving out the 'control'.*—In view of the apparent lack of uniformity in the data for the four groups, as explained above, it was thought desirable to confine the statistical analysis to the three treated groups only leaving out the 'control'. As the data were non-orthogonal, recourse was made to the method of 'Fitting of constants' for their analysis. The following Table II for the analysis of variance was constructed after evaluating the block and treatment effects and finding out, subsequently, the various sums of squares involved:

TABLE II

Analysis of Variance

Variance due to	D.F.	S.S.	M.S.	F. Ratio	5% point of F.
Blocks (ignoring treatments)	14	202·74	14·48	1·58	2·10
Treatments (adjusted for blocks)	2	35·36	17·68	1·93	3·37
Error	26	237·81	9·15	..	..
TOTAL ..	42	475·91			

The above table shows that neither the treatment nor the block mean square was significant as compared to the error. This implies that the treatments Nos. 2, 3 and 4 did not appear to be significantly different in inducing oestrum.

2. *Study on all the four treatments.*—The question whether chance could be the reason for the apparent inconsistency in the data for the 'control' group as compared to the other groups was investigated as follows:

A straightforward analysis of variance as above on all the four groups instead of three was first carried out and the results achieved were as follows:

TABLE III

Analysis of Variance

Variance due to	D.F.	S.S.	M.S.	F. Ratio	5% point of F.
Blocks (ignoring treatments)	14	152·90	10·92	0·89	1·95
Treatments (adjusted for blocks)	3	76·37	25·457	2·09	2·84
Error	40	487·21	12·180		
TOTAL ..	57	716·48			

It would be apparent from the foregoing table that the block variation was not significant. This means that the data for the four groups could be taken as random samples from possibly four different populations. The comparison of the variances of these four populations should reasonably give us a criterion for judging whether the data for the four groups were really inconsistent to justify a joint analysis of variance on all the four groups. If these variances did not differ significantly, there was every reason to believe that the differences were only due to chance effects. For this purpose a test of homogeneity of variances of these four populations was made. The value of χ^2 (chi-square) was found to be as low as 0·507. It was, therefore, concluded that these four variances did not differ significantly and thus a joint analysis of variance on all the four groups for the comparison of the four treatments appeared to be justified.

From Table III it was obvious that the treatments were not significant and that the calculated value of F in this case was slightly less than the value at the 5% level of significance while in the previous case the calculated value of F was very small and had a very high probability. This clearly showed that the difference in treatments, though not significant, tended to approach significance when 'control' was also included in the study. It was, therefore, reasonable to compare the means of the three treated groups with that of the untreated one, i.e. 'control'. This comparison showed that only treatment No. 3 (*bajra* plus gram) was significantly better than 'control', the result which would make it possible to recommend the feeding of a mixture of *bajra* and gram for increasing the frequency of oestrus in cattle.

3. *Estimation of missing values.*—To exploit the data for deriving some more useful inferences which might confirm the results already achieved it was thought desirable to restore the orthogonality of the data by estimating the two missing values. Recourse had, therefore, to be made to the 'Technique of the estimation of missing values' as evolved by Allan and Wishart (*1930*) and later generalized by Yates (*1933*). Employment of this technique was found quite reasonable in view of the fact that the two missing values occurred in the experiment merely due to random causes. On these grounds the problem was taken to be analogous to the one commonly arising in agricultural experiments where the yield of a plot or plots was occasionally lost or distorted by some disturbing factor beyond human control.

The two missing values were estimated both by approximate and exact methods. The values thus calculated were 2·03 and 2·73 respectively and with them the data were completed. The analysis of variance is given in Table IV.

From this study as well, it was clear that the calculated value of F (2·36) was slightly less than the value of F (2·84) at the 5% level of significance and it, therefore, completely corroborated the inference derived already in the previous case.

4. *Splitting the three degrees of freedom for treatments.*—For making a more detailed study of the data the three degrees of freedom assigned to

TABLE IV

Analysis of Variance

	D.F.	S.S.	M.S.	F. Ratio	Sum of squares calculated from
Total	57	716·483	..	..	Original data
Error	40	478·951	11·974	..	Completed data
Differences = Blocks + Treatments ..	17	237·532	..	..	..
Blocks	14	152·903	..	..	Original data
Differences = Treatments	3	84·629	28·209	2·36	..

treatments were further subdivided into three individual orthogonal degrees of freedom comprising the following three comparisons:

(i) Treatments (II+III+IV) ~ 3 I (Treated versus untreated).

(ii) Treatments (III+IV) ~ 2 II (Mixture versus no-mixture).

(iii) Treatment III ~ IV (*Bajra* versus *methi* seed).

After calculating the mean square for each of the above comparisons and comparing it with the error mean square it was found that only the first comparison, i.e. the treated versus the untreated, seemed to be significant at the 5% level of significance. It was, therefore, concluded that the feeding of a mixture of *bajra* and gram, due to its effectiveness, made the three treated groups as a whole to appear superior to the 'control'.

5. *Test of significance of the difference between the largest and the smallest means.*—To confirm the result already achieved the test of significance of the difference between the largest and the smallest means in a given group of sample means, as propounded by Tippett (1941), was employed. The range (the difference between the largest and the smallest means) and the standard error of difference in our case were calculated to be 3·26 and 1·27 respectively. Their ratio being just 2·6 (for a set of four means) was found to be significant at the 5% point according to the table prepared by Tippett for this purpose. This result, therefore, also confirmed the effectiveness of feeding a mixture of *bajra* and gram for the purpose in question.

DISCUSSION

It will be recalled that under the heading 'Previous work' we recorded only two references in which work on oestrus in cattle was mentioned. The first one was that of Tebbe (1935) who stated that a slimming diet may induce oestrus in cows. What actually constituted the so-called slimming diet, could not be ascertained as his original paper was not available anywhere in this country; nor could it be obtained from abroad. The second reference was that of Palmer *et al.* (1941) who concluded that a combined deficiency of phosphorus and protein in the bovines, analogous to similar deficiencies in animals reared largely on prairie hay in the phosphorus

deficient regions, delayed sexual maturity and repressed normal evidences of oestrum so that periods of oestrum appeared to be missed, but did not interfere with the normal regularity of ovulation or the ease of conception. These observations also run contrary to our own, as by chemical analyses the crude protein has been found to be less in *bajra* than in *methi*, while the former mixed with gram has been seen to be more effective for increasing the frequency of oestrus in cattle. It may, however, be pointed out that Makhijani (1944-45), working with goats in this Section, observed that *methi* seed containing more of protein was slightly better than *bajra* for increasing the frequency of oestrus.

The present experiment has further shown clearly that the interval between two successive heats in animals of the same breed and even of the same age varies considerably. The individual differences in the number of heats recorded from treatment to treatment and even within each treatment are so large as to warrant the statement that it is futile to assess the normal condition of oestrus in a breed by merely including a 'control' group for subsequent comparisons. In an experiment of such a nature, every individual animal should, therefore, have her own 'control' as the knowledge of her behaviour under normal conditions can possibly serve as the ideal 'control' which will enable a statistician to derive definite and precise conclusions after employing suitable statistical techniques. With this device the inconsistent 'within block variation' can also be avoided and properly accounted for, which, otherwise, is liable to vitiate the precision of the results.

In such experiments, it is ideal to study the oestrus in every individual animal for some reasonable period under normal conditions before they are given the proposed treatments. This would avoid the chance of losing some precision of the results by estimating certain missing values. This will also help in giving due consideration to the genetical differences between the various animals so far as frequency of oestrum is concerned. Finally, by using the number of heats per animal as a concomitant variate, the data will be easily analysed by the use of the well-known technique of 'Analysis of Covariance' and quite trustworthy results will be achieved.

Summary

1. In this investigation, feeding of a mixture of gram and *bajra* has been found to be quite effective for increasing the frequency of oestrus in cattle.

2. Some of the difficulties which are likely to be encountered in such investigations are presented in this paper.

3. A proper design of an experiment of this nature for tiding over some major difficulties is given.

4. Methods and suggestions for carrying out the statistical analysis of the data collected for such investigations have been put forth in detail.

Acknowledgments

The authors wish to express their sincere thanks to Shri B. N. Handa, B.Sc., M.R.C.V.S., the then Superintendent of the Government Livestock

Farm, Hissar, for his ever ready help and constant encouragement during the course of this investigation. They are thankful to Shri A. R. Roy, M.A., M.Sc., Statistician, Indian Council of Agricultural Research, for his valuable suggestions in carrying out the statistical analysis of the data. Thanks are also due to Dr. N. D. Kehar, Sc.D., Officer-in-Charge, Animal Nutrition Section, Indian Veterinary Research Institute, Izatnagar, for getting the samples of *bajra* and *methi* seed chemically analysed in his laboratories. They are also indebted to Major A. C. Aggarwala, B.Sc. (Hons.), M.R.C.V.S., A.I.R.O., Director, Veterinary Services and Warden of Fisheries, Panjab, for very kindly going through the manuscript of this paper. Lastly the grants from the Indian Council of Agricultural Research and the Panjab Government which made this investigation possible are also gratefully acknowledged.

THE SPERM OF *LEPISMA DOMESTICA*

By VISHWA NATH, *University Professor of Zoology, Panjab University, Hoshiarpur*

and

C. L. BHATIA, *Lecturer in Zoology, Government College, Ludhiana*

INTRODUCTION

In the last of the series of his epoch-making publications on insect spermatogenesis, Bowen (1924) gave a remarkable account of the formation of the sperm in Coleoptera (*Chelymorpha, Lixus* and *Cicindela*) and Aptera (*Lepisma domestica*) with a general discussion on flagellate sperms.

According to Bowen the sperm of *Lepisma* is an atypical flagellate sperm inasmuch as (1) the centrosome travels to the extreme anterior tip of the elongated nucleus, giving backwards an axial filament, which lies on the nucleus and then enters into the tail of the sperm, and (2) the acrosome, which is a product of the Golgi apparatus, remains at the base of the nucleus in the neck region, from where it sends backwards into the tail region a filamentary process, which gets lost along with the axial filament in the ripe sperm. In other words, the centrosome, which in typical flagellate sperms lies at the base of the sperm nucleus in the neck region, has, in *Lepisma* sperm, travelled to the extreme anterior tip of the nucleus, whereas the acrosome has departed from its typical position at the extreme tip of the nucleus, remaining in the neck region and sending backwards, instead of forwards, a long filamentary process.

Earlier Charlton (1921) had given an account of *Lepisma* sperm, which was surprisingly correct; but Charlton's homologies were all wrong due to the faulty technique he had used. According to Charlton also the centrosome migrated to the extreme anterior tip of the sperm nucleus, but, for the reason that the centrosome took up a position at the tip of the nucleus, he mistook it for the acrosome. Likewise, not knowing that the acrosome is always a product of the Golgi apparatus and puzzled by the unusual position of the acrosome, he mistook it for the 'middle-piece'. Again, considering that Charlton used fixatives containing fat-solvents, he gave a faithful account of the mitochondrial nebenkern as he saw it in his faulty preparations. It was subsequent to Charlton's publication that Bowen had given a very clear account of the origin, structure and ultimate fate of the mitochondrial nebenkern, particularly in insect spermatogenesis, as also of the origin of the acrosome from the Golgi apparatus in general.

Bowen's description of the sperm of *Lepisma* started a controversy which has not, up till this day, been settled. Gatenby and Mukerji (1929) and Mukerji (1929) questioned the findings of Bowen. According to these authors the spermatogenesis of *Lepisma* could be compared with the same

process as found in some other insects such as a Lepidopteran or a Cicindelid. Mukerji stated that Bowen, instead of trying to bring this *Lepisma* spermatogenesis in line with these insects, had gone so far as to suggest that the sperm of *Lepisma* was of an atypical type, differing in every respect from all other typical flagellate sperms. According to these authors what Bowen calls the acrosome in the neck region of the sperm is not the acrosome, but a new type of body, the post-nuclear body, 'as yet undescribed by all authors except Gatenby (1922 and 1929), who noted its presence in every type of spermatogenesis studied by him' (Mukerji 1929, p. 1). Mukerji goes on to say that their post-nuclear body is the 'middle-piece' of Charlton (1921).

Gatenby and Mukerji and Mukerji describe in both the papers a peculiar funnel-shaped structure immediately behind their post-nuclear body. This funnel-shaped structure has also been described and figured by Bowen (1924), but Bowen gives convincing evidence, which has been supported by our own observations, that the funnel is really a part of the attenuating acrosome, sending backwards in the tail region a filamentary process in later stages of spermateleosis.

Our observations on *Lepisma* spermatogenesis support Bowen's interpretations and homologies in every respect—the centrosome, the acrosome and the mitochondrial nebenkern. We have been fortunate in having a series of brilliant slides prepared by one of us (C. L. B.), which have enabled us to give, what we believe, is a correct account of the process. While supporting the homologies of Bowen we have filled up the gaps necessarily left by him. Likewise we have given reasons why we cannot accept the interpretations of Gatenby and Mukerji.

Work on the spermatogenesis of *Lepisma* was undertaken by one of us (C. L. B.) at the suggestion and under the supervision of the senior author at the Panjab University, Lahore, some years before August, 1947, when the partition of the Panjab took place. The work was completed at Lahore, but it could not be sent to the press before the partition. Some two years after the partition the junior author succeeded in bringing his *Lepisma* slides from Lahore. Subsequently he paid three visits to Hoshiarpur at wide intervals, when both the authors re-examined the slides. All the figures are prepared by C. L. B., but the manuscript has been prepared by the senior author.

The junior author obtained such brilliant preparations with Flemming-without-acetic followed by ·5% iron-haematoxylin that it was not considered necessary to use any other technique.

Observations

Spermatogonia and Spermatocytes :—

Although we have concentrated on the study of spermateleosis and have paid scant attention to earlier stages, it is necessary to examine the mitochondria and the Golgi elements in the spermatogonia and the spermatocytes.

In the spermatogonia (Pl. 1, fig. I) the Golgi elements exist in the form of vesicles, each vesicle showing a chromophilic cortex and a chromophobic medulla. In optical sections the Golgi vesicles appear either in the form of rings or crescents, each crescent generally showing the chromophobic sphere attached to it. It has not been possible to find any granules etc. in the spermatogonium, which can be assigned to the category of mitochondria; and we believe the mitochondria are differentiated for the first time in the primary spermatocytes.

In the primary spermatocytes also (Pl. I, fig. 2) the Golgi elements stain brilliantly and appear under the same forms as in the spermatogonia, but the mitochondria appear as a nebulous, juxta-nuclear mass of ill-defined granules.

Our material did not show any secondary spermatocytes or any spermatogonial and spermatocyte mitoses, but it abounded in different stages of spermateleosis. As we were concerned primarily with the maturing sperm, we did not consider it worth our while to prepare fresh preparations.

Spermateleosis :—

The earliest spermatid that we have been able to get has been drawn in Plate I, figure 3. The Golgi elements still lie scattered in the cytoplasm, but the mitochondria have fused together to form a deeply-staining, oval and curved mass, the mitochondrial nebenkern. A rod-shaped centrosome has appeared, which lies on the surface of the nucleus, giving rise posteriorly to the axial filament.

The mitochondrial nebenkern quickly assumes a spherical form and reveals a structure, which is highly characteristic of insect sperm, as shown by Bowen. It now consists of a deeply-staining medulla and a lightly-staining cortex, consisting of clear vacuoles (Pl. I, figs. 4, 7 and 13). But more often the medullary part of the mitochondrial nebenkern does not stain at all, with the result that the mitochondrial nebenkern is liable to escape notice altogether (Pl. I, figs. 5, 6, 8 to 10 and 12). The mitochondrial nebenkern now loses its duplex structure, and, since it has completely lost its staining capacity, it becomes increasingly difficult to demonstrate it for a long time. Indeed we have not figured it in figs. 15 and 16, Plate I. At a later stage, however, when the nucleus has completed its condensation and has lost its chromaticity, and the centrosome has placed itself at the anterior aspect of the nucleus, there can be noticed in a very small percentage of cells a faintly-staining, fusiform structure, stretching over the nucleus, between the centrosome and the acrosome, the latter lying immediately behind the nucleus (Pl. II, figs. 27 and 28). This is the degenerating mitochondrial nebenkern. But for the fact that the limits of the degenerating mitochondrial nebenkern are well-defined with the deeply-staining centrosome in front and the acrosome behind, and the nucleus provides an excellent background, it would have been almost impossible to demonstrate this structure. There can be no doubt whatsoever that the mitochondrial nebenkern completely pales off and disappears in the

later stages of spermateleosis. In one case only we have seen the mitochondrial nebenkern lying on the side of the pale nucleus, and taking up the stain (Pl. II, fig. 26).

When the mitochondrial nebenkern is passing through early stages of its formation as described above, most of the Golgi elements, *but by no means all*, come together to form the acrosome. Those Golgi elements, which do not co-operate in the formation of the acrosome, are ultimately sloughed off on entering the tail region of the sperm; but the acrosome-forming Golgi elements place themselves on the posterior side of the nucleus and, fusing together, form a prominent vesicular acrosome, which attaches itself closely to the posterior aspect of the nucleus (Pl. I, figs. 4 to 16). In figs. 13, 15 and 16, the large vesicular acrosome, clinging to the posterior side of the nucleus, is well represented; in fig. 12 the formation of the acrosome has been almost completed; in figs. 11 and 14 the vesicular nature of the acrosome-forming Golgi elements is well represented; and lastly in figs. 9, 10, 15 and 16 the Golgi elements, which did not co-operate in the formation of the acrosome, are seen being sloughed off in the tail region (*G'*).

It has to be noted that the vesicular acrosome, when first formed, shows a duplex structure consisting of an outer chromophilic cortex and an inner chromophobic medulla, exactly like the vesicular Golgi elements, which participated in its formation. But soon the acrosome begins to stain homogeneously; nevertheless it retains its spherical form (Pl. I, figs. 17 and 18).

Condensation of the acrosome continues till it becomes a shallow cup with a small process in its middle, sticking firmly to the posterior aspect of the nucleus (Pl. II, figs. 19, 20 and 21). By the elongation of this small process towards the posterior side, the cup-shaped acrosome is converted into a short, broad cone, which continues to stain deeply (Pl. II, figs. 22, 24, 25 and 27). The short, broad cone-like acrosome is gradually converted into a long, narrow cone (Pl. II, figs. 23, 26, 28 to 33, 35 and 39), till ultimately the apex of the cone-like acrosome is drawn out posteriorly into a long filament, which gets lost in the tail of the ripe sperm along with the axial filament, the upper broad part of the cone continuing to stick firmly to the posterior aspect of the nucleus (Pl. II, figs. 38 and 40).

The centrosome is recognizable as such for the first time in the earliest spermatid as a small thick rod, highly stainable, and giving off the axial filament (Pl. I, fig. 3). During the earlier stages of spermateleosis the centrosome keeps hovering in the vicinity of the nucleus generally towards its posterior aspect (Pl. I, figs. 4 to 10). But when the condensation processes within the nucleus have been completed and the nucleus begins to stain uniformly, the rod-like centrosome begins to travel forward, carrying the axial filament with it. A study of figs. 19 to 40 of Plate II will make this anteriorward migration of the centrosome very clear. In nearly ripe or ripe sperms (Pl. II, figs. 36 to 38 and 40) the rod-like centrosome is found to be placed at the extreme tip of the sperm nucleus. The axial filament runs over the surface of the elongated nucleus, and since the latter is sinuous the axial filament also takes a sinuous course. Behind the

nucleus the axial filament enters the sperm tail and gets lost along with the posterior filamentary process of the acrosome.

During the whole of this process of its migration anteriorward, the centrosome grows in size, becoming longer and thicker. On account of its elongated form, the centrosome is liable to break up into two, or even three, parts (Pl. II, figs. 29 and 32). We regard this breaking up of the centrosome as an artifact (*vide infra*).

Discussion

Our investigations confirm the findings of Bowen (1924) on the homologies of the various cell-components of the sperm of *Lepisma*.

There is complete consensus of opinion amongst the earlier investigators on the sperm of *Lepisma* with regard to the migration of the rod-like centrosome towards the anterior tip of the sperm nucleus, where it occupies a position generally assigned to the acrosome. Charlton (1921) clearly described this migration of the centrosome anteriorwards, but he mistook it for the acrosome on account of its unusual position at the tip of the elongated sperm nucleus. Besides Charlton seems to have been ignorant of the paper of Gatenby (1917), who for the first time had given a clear account of the direct origin of the acrosome from the Golgi elements, his *acroblasts*, in the sperm of the Lepidopteran, *Smerinthus*. Bowen (1924), Mukerji (1929) and Gatenby and Mukerji (1929) all confirm this migration of the centrosome anteriorwards. This unusual position of the centrosome at the anterior tip of the sperm nucleus in *Lepisma* is paralleled by the sperm of the tiger beetle *cicindela*, as worked out for the first time by Goldsmith (1919) and later confirmed by Bowen (1924). Our investigations on the *Lepisma* sperm also fully confirm these findings of the earlier investigators.

We agree with Bowen (1924) that 'in the primary spermatocytes there are numerous and unusually large scattered Golgi bodies.....' We also agree with him that 'in well-fixed spermatids the Golgi elements are very clearly demonstrated, each one being composed of a small mass of idiosomic material, to which is applied a darkly stained Golgi rodlet .....'. Bowen goes on to say that these spermatid 'Golgi bodies, at first scattered, may collect gradually into a more or less concentrated mass (fig. 92), they may remain for a time in a looser association (fig. 93), or they may be for quite a period rather widely scattered in smaller aggregates'. We entirely agree. If Bowen's figs. 92 and 93 are compared with our figs. 7 to 11 and fig. 14, it will be discovered that there is an essential agreement between us on this point. Bowen is quite correct in interpreting these clusters as clusters of Golgi bodies, which had been earlier considered by Charlton as derivatives of the mitochondria separated off from the nebenkern mass at an early stage in its condensation.

But we cannot agree with Bowen when he says that 'in addition, there occur in the cytoplasm several darkly stained granules (figs. 93 and 94) perhaps related to the *chromatoid body* (italics ours), and also rather ill-defined masses possibly to be compared with the *spermatid remnant*

(italics ours)'. Bowen goes on to say that these additional components (i.e., his chromatoid body and spermatid remnant) combine to make a very confusing cytoplasmic picture, but he does not consider them as Golgi material. On the contrary, without giving any reasons for building up new categories of cytoplasmic inclusions, he dismisses the 'chromatoid body' and the 'spermatid remnant' as unworthy of further consideration, and interprets in Charlton's figs. 80, 81 and 83 the body marked X as chromatoid granule of some kind, while the masses labelled *m* by Charlton are interpreted by Bowen as poorly preserved Golgi clusters for the most part.

We cannot agree with Bowen that the cytoplasmic picture offered by the maturing spermatid of *Lepisma* is confusing. Once it is understood that the Golgi elements, which are essentially granular and vesicular, may appear under different forms in fixed and sectioned material, there is no difficulty in regarding the 'chromatoid body' and the 'spermatid remnant' as the Golgi material. At any rate Bowen does not supply any information whatsoever with regard to the origin, morphology, fate and functions of his 'chromatoid body' and 'spermatid remnant.' On the contrary, he dismisses these bodies as unworthy of further consideration.

We invite comparison of Bowen's fig. 93 and our figs. 7 to 10 and 12. In Bowen's fig. 93 there is shown a darkly-staining spherical body on the left-hand side. This is presumably the 'chromatoid body' of Bowen; and admittedly this body has no fixed position in the cell. In our figures Bowen's chromatoid body appears in different forms, but it has been labelled by us as *G*, that is, the Golgi element. In fig. 7 it lies on the left of the nucleus and appears in the form of a ring; in fig. 8 it lies in front of the nucleus and consists of two tiny crescents; in fig. 9 it lies in the top corner of the cell on the left and appears in the form of a few granules; in fig. 10 also it appears as a granule immediately above the mitochondrial nebenkern; and in fig. 12 it appears in the form of three granules, one large and the other two small, lying immediately above the mitochondrial nebenkern.

Likewise we have had no difficulty in interpreting the 'spermatid remnant' of Bowen as the Golgi elements, which do not co-operate in the formation of the acrosome and are ultimately sloughed off. Bowen in his fig. 94 doubtfully labels his 'spermatid remnant' as S; whereas we have labelled the same material as *G'* in our figs. 9, 10, 15 and 16, that is, the sloughing-off Golgi material.

Before leaving the subject of 'chromatoid body' it will be profitable to dispose off references to this body made by Gatenby and Mukerji (1929). Even a casual study of the figures produced by these authors leaves no doubt that they are really describing the Golgi element under a different name. In their figs. 2, 5 and 7, Plate I, they have figured the 'chromatoid body' (*CB*), which is in fact, the Golgi element. In fig. 2 the 'chromatoid body' has been figured as a ring with rather a thick chromophilic cortex and a chromophobic medulla; in fig. 5 the cortex of the 'chromatoid body' (our Golgi element) is rather attenuated with a more prominent medulla; and in fig. 7 two small Golgi rings, touching each other, have been interpreted and labelled as the chromatoid body (*CB*).

We now address ourselves directly to that structure in the sperm of *Lepisma*, which has been described by Bowen (1924) as the acrosome. According to this author the acrosome of *Lepisma* sperm, which, like all other sperms, is formed by the Golgi elements, is unique inasmuch as it remains in the neck region. The same structure has been described earlier by Charlton (1921) as the 'middle-piece' and later by Gatenby and Mukerji (1929) and Mukerji (1929) as the 'post-nuclear body'.

We agree with Bowen that the acrosome of the sperm of *Lepisma* remains in the neck region, but we do not agree with him when he says that the acrosome is secreted by the Golgi elements (acroblasts). On the contrary, we have no doubt that the acrosome in the sperm of *Lepisma* is formed directly *by the fusion of vesicular Golgi elements.* We invite a reference to our figs. 11 to 16, Plate I, whose study, we believe, will make our point very clear. In figs. 11 and 14 the vesicular Golgi elements have come together to form the acrosome; in fig. 12 the large vesicular acrosome has been formed but its composite nature is still clear; and in figs. 13, 15 and 16 all traces of the composite nature of the acrosome have completely disappeared.

Indeed Bowen is himself doubtful about the acrosome being a secretory product of the Golgi elements (his acroblasts). In his figs. 93 to 95 he correctly shows the Golgi elements coming together, but 'this multiple construction of the acroblast makes it difficult to observe the actual deposition of the acrosome, which is perhaps deposited a little at a time as in the Lepidoptera'. Bowen admits that in the scanty material at his command, 'the steps in the deposition of the acrosome could not be followed satisfactorily; but once the process is well advanced, the acrosome becomes conspicuous as a more or less flattened, probably somewhat elongate, mass applied to the nuclear membrane at a point corresponding to the former position of the acroblast (figs. 97 and 98).' Bowen considers this mass to be homologous with the acrosomal granule of other forms, 'but I have not been able to make out the acrosomal vesicle, the occurrence of which one would expect.'

From the above it is clear that Bowen has not admittedly produced any evidence in favour of his theory of the acrosome being a secretory product of the acroblasts. Study of our preparations, on the contrary, has convinced us that the acrosomal mass, which Bowen considers 'to be homologous with the acrosomal granule of other forms', is a composite structure to begin with, formed as it is by the direct fusion of Golgi vesicles, and later this mass is converted into an acrosomal vesicle, which Bowen failed to observe in the scanty material at his disposal. A close study of Bowen's figs. 98, 99 and 106 to 108 leads one to suspect that his acrosome mass, which he has homologized with acrosomal granule, has after all a composite structure!

Nevertheless we strongly support Bowen's valuable conclusion that the acrosome, having been formed by the Golgi bodies, remains in the neck region, and corresponds to the 'middle-piece' of Charlton and to the 'post-nuclear body' of Gatenby and Mukerji.

We have also to make due allowance for the limitations of Bowen, considering that his conclusions are based on the study of Charlton's slides, which were admittedly prepared with fixatives containing fat-solvents. As stated by Bowen (1924) 'Charlton's attempts with specific Golgi technique were unsuccessful....'.

We believe that the use of fat-solvents by Charlton is also responsible for some of Bowen's conclusions with regard to the structural details of the mitochondrial nebenkern and its ultimate disposition in the sperm, with which we cannot agree. It will be recalled that in late stages of spermatelcosis we have described the nebenkern as a fusiform and faintly-staining structure stretching over the surface of the nucleus with the centrosome in front and the acrosome behind (Pl. II, figs. 27 and 28). A reference to Charlton's figure 87, Plate 6, will make it clear that this author also has defined the limits of the nebenkern in an identical manner,—that is, the centrosome (his acrosome) at the anterior end and the acrosome (his middle-piece) at the posterior end of the nebenkern. But Bowen figures (fig. 107, Pl. 4) the nebenkern as extending beyond the acrosome into the tail-region of the sperm. We cannot agree with this part of Bowen's conclusion. We believe that the nebenkern does not extend beyond the acrosome behind; and as we have already stated it completely disappears from view, whereas, according to Bowen, it forms the sheath of the axial filament of the tail. We must, however, state, in fairness to Bowen, that neither Charlton nor we have ever been able to get that fine differentiation of stain in the tail region of the sperm behind the acrosome which Bowen obtained in his figure 87, Plate 6, and in all our figures in Plate II, the tail region consists of deeply-staining acrosome in front and the fine axial filament behind.

Nor did we ever get the stage of the nebenkern as figured by Bowen in his figure 95, Plate 4, where the nebenkern has considerably elongated and the 'central substance', which consists of delicate vesicles, has appeared in its interior. In our preparations (see our figs. on Plate I), the nebenkern remains spherical and simply pales off; and it can be seen in a very small percentage of cells at a much later stage as an almost hyaline and fusiform structure stretching over the surface of the nucleus between the centrosome in front and the acrosome behind.

But the 'central substance' of Bowen is conspicuous by its absence in our preparations. While going through Bowen's paper one gets the impression that Bowen, while recording some of his statements, was unconsciously influenced by what he had seen and described earlier in other insect orders, such as the Lepidoptera and the Hemiptera, in which there is a typical mitochondrial nebenkern.

It may be that Bowen has mistaken the vacuolar system described by Mukerji (1929) for the 'central substance'. According to this author there is a system of neutral red-staining vacuoles, consisting of small vesicles aggregated together, as in the germ-cells of *Abraxes, Cavia, Saccocirrus* and *Macrothylacia*. In *Lepisma* the vacuoles are ultimately thrown down the tail.

Our belief that Bowen has mistaken these delicate vacuoles for his 'central substance' is strengthened by the study of our figures 9 to 11, Plate I, in which we have figured delicate vacuoles (*V*) in the tail region independent of the nebenkern.

While our observations support the broad conclusions arrived at by Bowen, we must strongly controvert the conclusions of Gatenby and Mukerji (1929) and Mukerji (1929), viz., (1) the acrosome in the *Lepisma* sperm lies as usual at the anterior tip of the nucleus and (2) the 'acrosome' of Bowen or the 'middle piece' of Charlton is the 'post-nuclear body'.

Talking of the centrosome in *Lepisma*, Bowen (1924) says that this rod-shape is retained by the centriole in all the subsequent stages which have been studied and there is practically no indication of a division into two parts such as commonly occurs in the spermatid. But 'rarely, at about the stage of figure 109, I found an apparent division of the rod into two rather distinct, elongate granules—possibly indicative of a potential duplicity in the outwardly single centriole'. Charlton (1921) also describes the breaking up of the centrosome into two or three parts.

We have also noticed in a few cases a similar breaking-up of the rod-shaped centrosome into two or three parts (Pl. II, figs. 29, 32 and 33), which we consider to be an artifact. We are convinced that Gatenby and Mukerji (1929) have mistaken the anterior part of the centrosome for the acrosome. Indeed these authors also describe the breaking up of the centrosome in two parts (their fig. 6, Pl. I). In their figure 4, Plate I, they seem to have misinterpreted the anterior of these two granules as the acrosome! Again Gatenby and Mukerji have failed to establish the origin of their 'acrosome' from the Golgi bodies, as was done by Bowen, whose observations we have fully supported. Both Bowen and the present writers have shown numerous Golgi bodies in the neck region where they form the acrosome, which continues to remain in this region of the sperm. After all a structure cannot be called an acrosome unless it is proved to have its origin in the Golgi bodies.

In addition to the 'post-nuclear body', which is really the acrosome, Gatenby and Mukerji have described a clear funnel-shaped structure, the 'post-nuclear funnel', which lies immediately behind their 'post-nuclear body'. This funnel has neither been described by Charlton, nor by Bowen, nor again by the present writers. Judging from the very scanty data furnished by Gatenby and Mukerji, one gets the impression that their preparations are not satisfactory. A reference to our figures on Plate II will show that the acrosome, when fully developed, is a funnel-shaped structure, staining deeply with iron-haematoxylin. We are inclined to believe that Gatenby and Mukerji have failed to stain this funnel-shaped acrosome except its anterior part, which they have called as the 'post-nuclear body', and the posterior unstained part as the 'post-nuclear funnel'.

If the 'post-nuclear body' of Gatenby and Mukerji (1929) in the *Lepisma* sperm is the acrosome, that of *Cavia* as described by Gatenby and Wigoder (1929) is nothing but the posterior region of the nucleus. This was reported by Nath (1944) in his Presidential address to the Section

of Zoology and Entomology, 31st Indian Science Congress held at Delhi. It will be profitable to quote what Nath said:

'Reverting to the silver methods, I feel no hesitation in saying that these methods, in spite of the occasionally brilliant results they have yielded, have grievously led us astray with respect to the form of the Golgi apparatus. But what is worse is that these methods (and also the long osmication methods) can blacken mitochondria, nuclear membrane and several other structures in the cell totally unrelated to the Golgi apparatus (see Bowan, 1928*b* for this phenomenon). Indeed it appears that granules of silver and osmium can settle down on many kinds of surfaces. Friend (1935), working on the sperms of British Muridae, discovered that there was an asymmetrical deeply staining area in the posterior part of the nucleus in all the Muridae sperms he had seen, which gave the characteristic stain with Feulgen. He named this area as the "dense posterior region", and he pointed out that in position it agreed with Gatenby's "post-nuclear body". G. W. Vaidya, the King Edward Memorial Scholar from Nagpur working at Lahore on the sperm of the squirrel, has confirmed Friend's conclusions. He employed Feulgen's reaction on smears and sections fixed in about seventeen fixatives. The posterior part of the nucleus in each case took up the characteristic stain, showing that the "post-nuclear body" is only a part of the nucleus. In Da Fano (chilled) preparations no post-nuclear granules were observed in any stage of spermatogenesis, but in Da Fano smears silver was deposited on the posterior part of the nucleus. Gian Chand has arrived at identical results in the sperm of Cavia.'

The degeneration of the fully-formed acrosome in the non-flagellate sperm of *Paratelphusa spinigera* and its allies has been reported by Nath (1932 and 1942), who also reported in several species of the Decapod sperm the complete degeneration of the Golgi elements *before* they have had a chance to form the acrosome.

But *Lepisma domestica* seems to be the first case on record of the complete paling off of the fully-formed mitochondrial nebenkern. The climax seems to have been reached in the spermatogenesis of a local dragon-fly, in which Rishi (unpublished) has reported in this laboratory a complete absence of the mitochondrial material in the spermatid—not to talk of the mitochondrial nebenkern!

Summary

1. We are in general agreement with the broad conclusions of Bowen (1924) on the spermateleosis of *Lepisma domestica*, although we have important differences of detail.

2. We have been able to confirm the important discovery of Bowen that the acrosome of the *Lepisma* sperm remains in the neck region, from where it sends backwards into the tail region a filamentary process, which gets lost with the axial filament.

3. But, according to our investigations, on *Lepisma* sperm, the acrosome is formed by the direct fusion of the Golgi vesicles and is not a secretory product thereof as described by Bowen.

4. The 'chromatoid body' of Bowen, Gatenby and Mukerji (1929) and Gatenby (1929) is only that part of the Golgi apparatus, which does not merge into the acrosome. The 'spermatid remnant' of Bowen also represents the non-participating Golgi elements, which are ultimately sloughed off down the region of the sperm tail.

5. The structure described as acrosome by Bowen corresponds to the 'middle-piece' of Charlton (1921) and to the 'post-nuclear body' of Gatenby and Mukerji, and Mukerji.

6. The 'post-nuclear funnel' of Gatenby and Mukerji, and Mukerji is again the posterior part of the funnel-shaped acrosome, which they have failed to stain.

7. The rod-shaped centrosome gets itself placed at the extreme anterior tip of the attenuated nucleus, from where it sends back, on the side of the nucleus, an axial filament, which enters the sperm tail behind the nucleus.

8. Bowen, Charlton, and the present authors—and even Gatenby and Mukerji, and Mukerji—report the breaking up of the rod-shaped centrosome into two or three parts. The last-mentioned authors seem to have mistaken one of these parts of the centrosome as the acrosome.

9. A typical insect mitochondrial nebenkern is formed in *Lepisma*, but it seems to pale off and disappear completely without forming the sheath of the axial filament in the typical insect manner. This is contrary to Bowen's conclusions.

VISCOSITY OF CONDENSED PHOSPHATES IN SOLUTION

By Ram Chand Paul, Kundan Lal, V. S. Gaind *and* S. S. Bawa

As early as 1833, T. Grahm [1] demonstrated the existence of three different types of sodium metaphosphates: glassy soluble metaphosphates, crystalline soluble metaphosphate, and insoluble metaphosphate. Glassy metaphosphate was also described in some details by Proust.[2] An early paper interesting because of its insight into polymeric aspects of the structure of condensed phosphates and their hydrolytic instability in the presence of acids is that of Flietmann and Hanneberg.[3] That a century of work following these earlier papers only resulted in creating confusion about the chemistry of metaphosphates is apparent from the many contradictory systems of nomenclature adopted by various authors during this period. Most of the trouble can, however, be traced back to the inadequacy of the methods used in establishing the chemical individuality and to assign the degree of polymerization. In recent years a number of helpful reviews have been made.[4] Mention may also be made of the two modern experimental papers [5] which have thoroughly dealt with the phase equilibria of the system Na_2O–P_2O_5 in the range $NaPO_3$–$Na_4P_2O_7$. Recently Monk and Davies [6] and Lamm [7] have shown that the so-called sodium hexa metaphosphate is in fact a polymer with molecular weight of about 13,000, e.g. 130 units of $NaPO_3$. It has also been noticed that some of the condensed phosphates give highly viscous solutions. But a comparative study of the viscosities of different solutions of condensed phosphates has not been made. In the present work attempt has been made to do so and to estimate roughly the molecular size of the phosphate polymers by applying the well-known Staudinger's equation [8] relating intrinsic viscosity with molecular weight. Much work has been done on organic polymers by Staudinger and others (*loc. cit.*) who have concluded that the equation

$$(\eta) = KM^a \qquad .. \qquad .. \qquad (1)$$

gives results with a close degree of approximation as long as the solute-solvent system remains the same in cases of polymers with molecular

weight higher than 10,000. In the present work an attempt has been made to keep the solute-solvent system same.

Nomenclature used is the one suggested by E. Partridge.[1]

Experimental.—Preparation of metaphosphates.

Sodium (1 : 1) phosphate glass I.—Two different methods that of Monk and Davies (*loc. cit.*) and Pascal[2] were used for preparing this sample. Both the products gave similar results. Other sodium metaphosphates were prepared according to the method described by Topley.[3]

Sodium metaphosphate II.—Dehydrated NaH_2PO_4 was heated for 10–12 hours at 350–380°C. in an electric oven.

Sodium metaphosphate III.—This is obtained mixed with $NaPO_3$ I and the unchanged sodium phosphate when dehydrated NaH_2PO_4 is heated for 8 hours at 250–280°C. The soluble impurities were removed by repeated washings with water in which $NaPO_3$ III is insoluble.

Sodium metaphosphate IV.—The sodium metaphosphate melt was cooled to 500°C. till crystallization began. It was then heated to 550–600°C. to promote crystallization and formation of a fibrous mass. This was then washed with water to remove soluble impurities. The insoluble crystals thus obtained were used to provide nucleus for another melt cooled to 550–600°C. The ratio of Na_2O/P_2O_5 in these melts was about one and the fibrous mass could be obtained only after six attempts. The potassium metaphosphates were prepared by the method of Lamm and Malmgrem.[4]

Potassium 1 : 1 phosphate glass.—It was prepared by fusing KH_2PO_4 in a platinum dish, keeping it in a molten state for 4-5 hours and then cooling abruptly.

Potassium Kurrol salt.—It was prepared by heating KH_2PO_4 in a dish at 350–380°C. The same product was obtained by sintering KH_2PO_4 over a mecker burner for half an hour.

Potassium trimeta phosphate.—It was got by heating KH_2PO_4 (dehydrated) for ten hours at 170–180°C.

Preparation of solutions.—In case of insoluble metaphosphates the solutions were made by dissolving the powdered samples in minimum amount of 5% NH_4Cl solution. When completely dissolved, precipitation of the phosphate was effected by addition of alcohol to cold solution and allowing it to crystallize over night. The precipitated phosphate was then filtered, redissolved in water and reprecipitated by adding alcohol. The filtered sample was washed with alcohol, dried in vacuum and its solution in water used for viscosity determinations. Reprecipitation was necessary to eliminate the electrolytes in the presence of which viscosity is known to decrease a good deal. Malmgrem (*loc. cit.*) found that although the molecule becomes stable in Na CNS solution, the molecular size actually decreases and becomes stable at a lower value.

Apparatus.—An Ostwald type viscometer constructed according to the design of Fenske and Cannon [1] to eliminate drainage and tilting error was used. Since it had a flow time of about 220 seconds with water no kinetaic error correction was applied and kinematic viscosity could be obtained directly from the time of flow. The temperature of the bath was kept at 25°C. (±0·05°.)

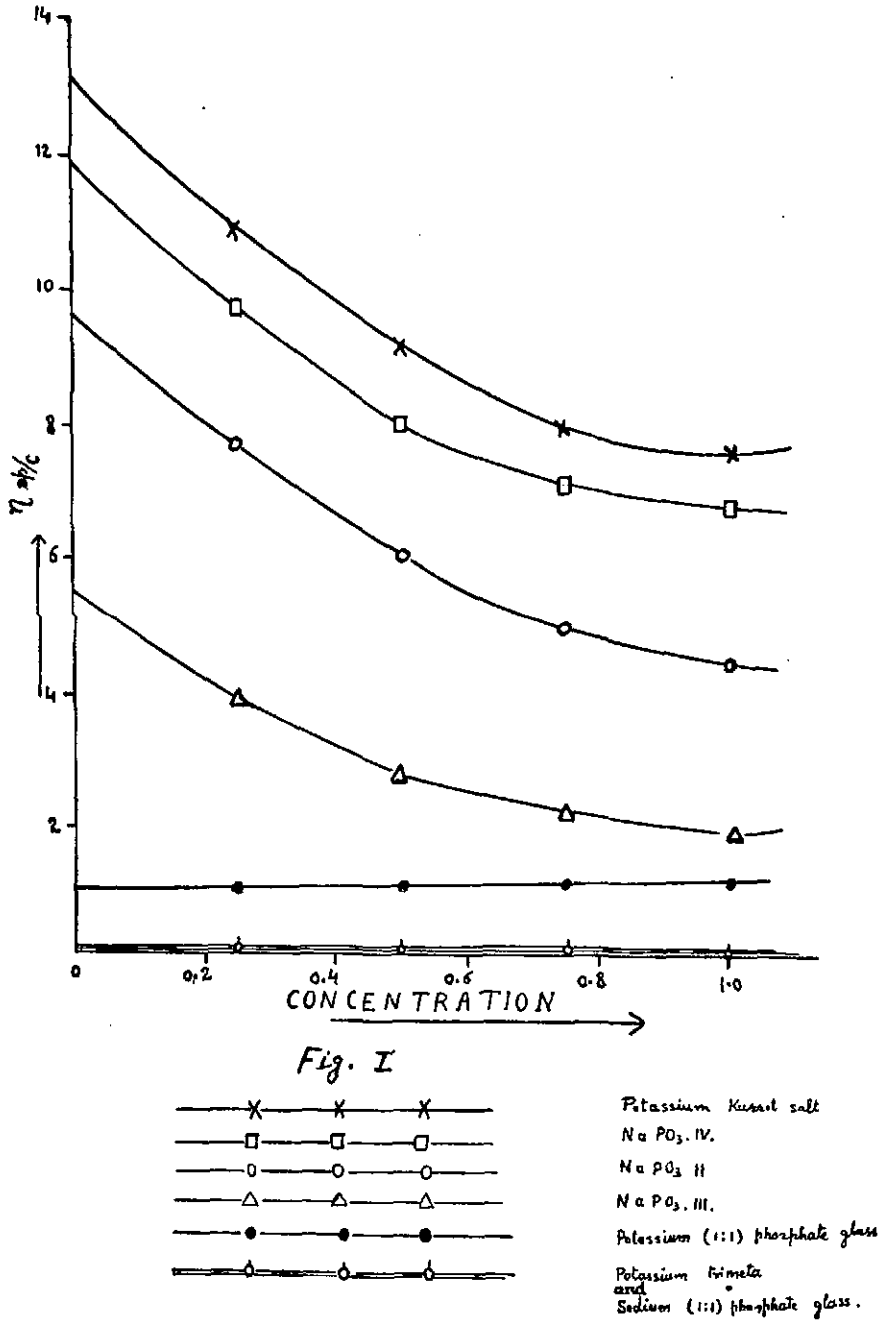

Fig. I

[1] Fenske and Cannon, *Ind. Engg. Chem. Analyst. Ed.*, 1938, **10**, 192.

Results and discussion.—The results have been tabulated in Table I. The relative viscosity, specific viscosity and the ratio of sp. visc. to concentration are shown against concentration of the solutions. In fig. I $\eta_{sp.}/C$ is plotted against C. Unlike organic polymers, slight curves are obtained. This is in accord with the results of earlier authors[1] who have worked with similar molecules. The curves have been extrapolated to infinite dilution to obtain the value of intrinsic viscosity. Substituting this in equation (1), the values of mol. wts., have been calculated and are given in Table II. The constants K and a in the equation (1) were calculated by substituting the values of molecular weights of sod. 1 : 1 *phosphate glass and potassium Kurrol as found by Malmgrem.*[2]

From the results it is noticed that all the phosphates which are insoluble in water show high mol. wts., e.g. greater degree of polymerization. The insolubility is probably due to the enormous size of the molecules. The values of mol. wts. can only be approximate due to the inherent character of the method that has been used and also due to the process of solvation of the samples during which the substances have sometimes been warmed with NH_4Cl solution. NH_4Cl has been selected preferentially for solvation due to the ease with which it can be estimated quantitatively. The rôle of NH_4Cl in bringing about the dissolution of the insoluble phosphates is under investigation.

ANTIMALARIALS IN QUINAZOLONE SERIES

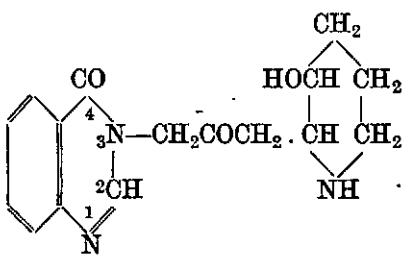
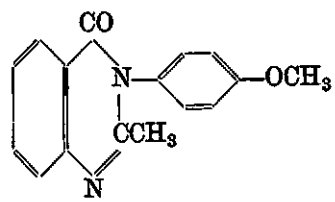
By Megh Kumar Jain *and* K. S. Narang, *Chemistry Department, Panjab University College, Hoshiarpur*

Febrifugine (I) is a 4-quinazolone having a basic side chain at 3. The remarkable antimalarial activity of febrifugine, namely 100 *Q—E*, led us to synthesize a few 3-substituted 4-quinazolones. In fact, the compound (II), synthesized already in these laboratories, has been found to be as active as quinine when tested against *P. gallinaceum* in chicks.



(I)



(II)

The present communication records the preparation of some 2, 3-substituted 4-quinazolones (Table I). Details will, however, be published later on.

Acknowledgement.

The authors wish to express their gratefulness to Dr. S. M. Mukherji for all the keen interest he showed in this work.

POTENTIOMETRIC STUDIES IN OXIDATION-REDUCTION REACTIONS

PART XVI. OXIDATION WITH CHLORAMINE-T. DETERMINATION OF ORGANIC SUBSTANCES

By BALWANT SINGH, APAR SINGH *and* MOHAN SINGH

Noll (1924) described the use of chloramine-T as an oxidizing reagent. The solid salt has the composition

$$p\text{-}CH_3.\,C_6H_4.\,SO_2.\,N\begin{matrix}Na\\Cl\end{matrix}.\,3H_2O$$

In solution it behaves like a stable hypochlorite

$$CH_3.\,C_6H_4.\,SO_2.\,N\begin{matrix}Na\\Cl\end{matrix}+H_2O = CH_3.\,C_6H_4.\,SO_2.\,NH_2+NaCl+O$$

Rupp (1925, 1928) used chloramine-T for the determination of trivalent antimony, and later for the titration of stannous tin.

Tomicek and Sucharda (1932) used it as a reagent for the potentiometric determination of tervalent arsenic and antimony; bivalent tin and iron and the ferrocyanide and iodide ions; and for the visual titration of tervalent arsenic and antimony, using methyl red as an indicator.

Komarovskii, Filonova and Korenman (1933, 1934) have shown that chloramine-T can be used as a volumetric reagent to replace the more expensive iodine and the less stable hypochlorite in the estimation of ferrocyanide, hydrazine and hypophosphite. B. Singh and A. Rehmann (1940) have used chloramine-T for the determination of hydroquinone, quinhydrone, hydrazine hydrochloride, potassium iodide, sodium bisulphite and sodium nitrite by a potentiometric method. Thomas Lee, Holzmann, Swift and Neimann (1948) used chloramine-T in the quantitative estimation of various organic sulphides.

B. N. Afanas'ev (1949, 1950) has shown that chloramine-T is a suitable reagent for determining many organic compounds by oxidative volumetric procedures, using methyl red or indigo carmine as an indicator.

In the present investigation chloramine-T has been used for the potentiometric estimations of vanilin, *p*-hydroxy benzaldehyde, benzaldehyde, salicylaldehyde, acetaldehyde, furfural, urea, oxalic acid, thio-urea, glycerol and mannitol.

The aldehydes are oxidized with chloramine-T in a strongly alkaline medium, urea in a weak alkaline medium, and the rest in an acidic medium. These compounds are oxidized according to the following equations:—

1. *VANILIN.*

$$CH_3.\ C_6H_4SO_2N\begin{matrix}Na\\Cl\end{matrix} + CH_3O.\ (OH).\ C_6H_3CHO + NaOH$$
$$= CH_3.\ C_6H_4SO_2NH_2 + CH_3O.\ (OH).\ C_6H_3COONa + NaCl$$

2. *p-HYDROXY BENZALDEHYDE.*

$$CH_3C_6H_4SO_2N\begin{matrix}Na\\Cl\end{matrix} + HO.\ C_6H_4CHO + NaOH$$
$$= CH_3.\ C_6H_4SO_2NH_2 + HO.\ C_6H_4COONa + NaCl$$

3. *BENZALDEHYDE.*

$$CH_3.\ C_6H_4SO_2N\begin{matrix}Na\\Cl\end{matrix} + C_6H_5CHO + NaOH$$
$$= CH_3.\ C_6H_4SO_2NH_2 + C_6H_5COONa + NaCl$$

4. *SALICYLALDEHYDE.*

$$CH_3.\ C_6H_4SO_2N\begin{matrix}Na\\Cl\end{matrix} + C_6H_4(OH)\ CHO + NaOH$$
$$= CH_3.\ C_6H_4SO_2NH_2 + C_6H_4(OH)\ COONa + NaCl$$

5. *ACETALDEHYDE.*

$$CH_3.\ C_6H_4SO_2N\begin{matrix}Na\\Cl\end{matrix} + CH_3CHO + NaOH$$
$$= CH_3.\ C_6H_4SO_2NH_2 + CH_3COONa + NaCl$$

6. *FURFURAL.*

$$CH_3.\ C_6H_4SO_2N\begin{matrix}Na\\Cl\end{matrix} + C_4H_3(O)\ CHO + NaOH$$
$$= CH_3.\ C_6H_4SO_2NH_2 + C_4H_3(O)\ COONa + NaCl$$

7. *UREA.*

$$3\ CH_3.\ C_6H_4SO_2N\begin{matrix}Na\\Cl\end{matrix} + H_2O + OC(NH_2)_2$$
$$= 3\ CH_3.\ C_6H_4SO_2NH_2 + 3\ NaCl + N_2 + CO_2$$

8. *OXALIC ACID.*

$$CH_3.\ C_6H_4SO_2N\begin{matrix}Na\\Cl\end{matrix} + \begin{matrix}COOH\\|\\COOH\end{matrix} = CH_3.\ C_6H_4SO_2NH_2 + NaCl + 2\ CO_2$$

9. *THIOUREA.*

$$7\,CH_3.\,C_6H_4SO_2N\begin{matrix}Na\\Cl\end{matrix} + 6\,H_2O + SC(NH_2)_2$$
$$= 7\,CH_3.\,C_6H_4SO_2NH_2 + 7\,NaCl + N_2 + CO_2 + H_2SO_4$$

10. *GLYCEROL.*

$$7\,CH_3.\,C_6H_4SO_2N\begin{matrix}Na\\Cl\end{matrix} + 3\,H_2O + C_3H_8O_3$$
$$= 7\,CH_3.\,C_6H_4SO_2NH_2 + 7\,NaCl + 3\,CO_2$$

11. *MANNITOL.*

$$13\,CH_3.\,C_6H_4SO_2N\begin{matrix}Na\\Cl\end{matrix} + 6\,H_2O + C_6H_{14}O_6$$
$$= 13\,CH_3.\,C_6H_4SO_2NH_2 + 13\,NaCl + 6\,CO_2.$$

Experimental

Standardization of Chloramine-T Solution.

25 c.c. of the solution were acidified with 5 c.c. of 2*N* hydrochloric acid and 10 c.c. of ten per cent potassium iodide solution were added to it.

$$CH_3.\,C_6H_4SO_2N\begin{matrix}Na\\Cl\end{matrix} + 2\,HI = CH_3.\,C_6H_4SO_2NH_2 + NaCl + I_2$$

The liberated iodine was titrated against standard sodium thiosulphate solution.

Potentiometric Titrations.

A known weight of an aldehyde was dissolved in aqueous alcohol and the solution was made alkaline with sodium hydroxide. This was titrated against standard chloramine-T solution. The alcohol did not interfere in the oxidation. B. N. Afanas'ev has shown that methyl alcohol and ethyl alcohol are not oxidized by chloramine-T under any conditions.

A known weight of urea was dissolved in water and was titrated against chloramine-T solution in the presence of sodium bicarbonate.

Aqueous solutions of glycerol, mannitol, oxalic acid and thiourea were acidified with sulphuric acid and titrated against chloramine-T.

The reaction mixture was kept stirred by means of a mechanical stirrer and the progress of the reaction was studied potentiometrically. A bright platinum foil was used as an oxidation-reduction electrode and this was coupled with a saturated calomel electrode through an agar-agar potassium chloride bridge.

A series of potentiometric titrations were performed with different amounts of each substance. One titration for each substance, as typical of that set, is recorded in the following tables:—

TABLE I

Titration of 0·1140 gms. of vanilin mixed with 63 c.c. of aqueous alcohol and 0·096 gms. of NaOH, against 0·0456 M chloramine-T.

DISCUSSION

It is evident from the foregoing tables that there was a sharp break in E.M.F. in each potentiometric titration at the equivalence-point. From the amount of chloramine-T required in each titration, corresponding to the equivalence-point, the amount of the substance was calculated. In the following tables the values obtained are compared with the amounts of the substances taken for the titrations:

SPERMATELEOSIS IN THE DRAGON-FLY *SYMPETRUM HYPOMELAS* (SELYS)

By Vishwa Nath *and* Rajindar Rishi, *Department of Zoology, Panjab University, Hoshiarpur*

Introduction

In November, 1952, S. R. Bawa, Panjab University Research Scholar working in this Department, gave to one of us (R.R.) a paraffin block of the testicular material of the local dragon-fly, fixed in Flemming—without —acetic. On cutting the block and staining with 0·5% iron-haematoxylin it was observed that the material abounded in spermatids and sperms, but, to our great surprise, the mitochondrial material was conspicuous by its complete absence—not to talk of the typical insect nebenkern, which one comes across in the spermateleosis of the Hemiptera, Lepidoptera, Coleoptera, Orthoptera and even of such wingless primitive insects as the silver-fish, *Lepisma*.

In a very recent publication Nath and Bhatia (1953) have attempted to solve the very controversial homologies of the *Lepisma* sperm, and have demonstrated the complete degeneration of the mitochondrial nebenkern *in this atypical sperm. But in the dragon-fly, Sympetrum hypomelas*, which forms the subject of the present investigation, the mitochondrial material seems to be completely absent even in the spermatogonia and spermatocytes. This material is also unusually favourable for the demonstration of the direct origin of the acrosome from the acroblast, which is formed by the fusion of a number of Golgi granules.

Subsequently more material was fixed in F.W.A., and sections stained with 0·5% iron-haematoxylin; but throughout winter the material consistently lacked in dividing spermatogonia and spermatocytes.

Our thanks are due to Dr. Rattan Lal of the Indian Agricultural Research Institute, New Delhi, for having identified the dragon-fly.

Observations

Spermateleosis

In the earliest spermatid (Pl. I, Figs. 1 and 2) the nucleus lies at one pole of the cell, and its chromatin content is lightly stained. The mitochondrial substance is conspicuous by its absence, but a few prominent, darkly-staining Golgi bodies are invariably met with in the cytoplasm.

In the next stage the chromatin is condensed and the nucleus becomes darkly staining. When the chromatin starts condensing the nucleus loses its spherical form and appears irregular (Pl. I, Fig. 3), but later on it again becomes spherical (Pl. I, Fig. 4). The nucleus which, to begin with, is in

close contact with the cell wall now comes to lie almost in the middle of the cell.

Meanwhile the Golgi bodies start fusing. From three or four separate bodies they form two Golgi masses first, and eventually their fusion is completed by the formation of a single mass of the Golgi material (Pl. I, Figs. 3 and 4). At this stage the Golgi mass lies away from the nucleus as a distinct spherical body (Pl. I, Fig. 4).

This Golgi mass now moves towards one side of the nucleus (Pl. I, Fig. 6), but, sooner or later, it places itself on the anterior aspect of the nucleus, where it applies itself firmly to the nuclear membrane (Pl. I, Figs. 7 and 8).

The earlier history of the centriole could not be traced, but once the axial filament has put in its appearance, the centriole can be very clearly made out as a darkly staining granule at the base of the nucleus (Pl. I, Fig. 8).

A remarkable feature of the axial filament is that it never emerges out of the cytoplasm of the maturing spermatid; hence it remains short (Pl. I, Figs. 13 to 15). Indeed the tail of the ripe sperm is ridiculously short as compared with the length of the nucleus (Pl. II, Figs. 37 and 38).

Meanwhile the Golgi mass, lying at the anterior end of the nucleus, is bodily transformed into the acrosome of the ripe sperm. The first step in this transformation is the appearance of a very lightly staining triangular area, the Golgi mass, now reduced in size, lying at the apex of the triangle (Pl. I, Figs. 9 to 12). The acrosomal triangle never grows to a considerable size, but it invariably shows a tiny granule, perched at its free tip: this is *the Golgi mass, which has undergone progressive reduction in its size* (Pl. I, Figs. 16 to 22 and Pl. II, Figs. 37 and 38).

When the formation of the acrosome is almost complete the cell starts elongating along the axial filament (Pl. I, Figs. 13 to 15). During this stage the axial filament can be clearly made out with the cytoplasmic sheath round it, but in subsequent stages, when the tail gets more attenuated, the axial filament as such completely disappears from view.

We left the spermatid nucleus at a stage when it becomes spherical and stains deeply and uniformly with haematoxylin (Pl. I, Fig. 4). After the acrosome has been differentiated from the Golgi mass at the anterior end of the nucleus, the latter begins to elongate, passing through pyriform, ovoid, dumbell-shaped, and even club-shaped forms (Pl. I, Figs. 17 to 24).

During the process of its elongation the nucleus is darkly stained. In the over-differentiated elongating sperms, however, the nucleus appears highly vacuolated (Pl. I, Fig. 25 and Pl. II, Fig. 26). The vacuolar appearance of the nucleus depends largely on the extent to which the stain has been extracted. These vacuoles are very small and closely packed together. They give an appearance of a net-work (Pl. II, Fig. 26). In some cells chromatin is condensed at the two poles of the nucleus with a central vacuolated region (Pl. II, Figs. 26 and 28). Sometimes, however, the chromatin is aggregated at one pole only (Pl. II, Fig. 27).

At a still later stage a prominent rod is seen traversing the nucleus. It joins the two chromatin masses (Pl. II, Fig. 28). At first the rod is rather

kinky, and it seems that it has been formed by the condensation of the chromatin reticulum in the central region (Pl. II, Fig. 28). Gradually it smoothens up into a more or less wavy outline (Pl. II, Fig. 29), but eventually it straightens up to form a straight axial core of the sperm nucleus (Pl. II, Fig. 30).

A certain amount of faintly staining material can be observed in the maturing sperm-tail near the base of the nucleus (Pl. I, Figs. 19, 20 and 22). It soon condenses to form more darkly stained granules, which travel from the base of the nucleus to the posterior tip of the tail (Pl. I, Figs. 21 and 24 and Pl. II, Figs. 27 and 34). They undoubtedly represent some residual material, which is ultimately sloughed off. In view of the fact that there are no mitochondria and *all* the Golgi granules fuse to form the acrosome, it is conjectured that the residual substance thrown out along the tail is nuclear in origin. This view is strengthened by the important observation that these remnants first of all appear near the base of the nucleus and then travel downwards.

The club-shaped form of the nucleus gradually leads to the rod form (Pl. II, Figs. 31 and 32). Even at this stage, if the sperm nucleus is over differentiated, it shows a vacuolated condition (Pl. II, Fig. 33).

Meanwhile the acrosome elongates to its maximum length but even now a granule can be observed at its tip, which is in the form of a minute speck. In the final stage the nucleus attains a considerable length by further elongation and becomes a narrow rod (Pl. II, Figs. 34 to 37).

In the ripe sperm the acrosome is very prominent with a distinct minute granule at its tip. The nucleus is long and narrow and is now less darkly staining than before. The tail is very small as compared to the length of the head (Pl. II, Fig. 38).

Early Stages

As mentioned previously, the material was fixed in winter months (November to March) at different times. In all the preparations the earlier stages, i.e. the spermatogonia and the spermatocytes, were very rare. The mitotic and meiotic stages were completely absent.

Spermatogonia

The earliest spermatogonia of the dragon-fly are large, more or less, rounded, or oval cells with comparatively large nuclei. The nucleus, which reveals inside it one or two darkly staining chromatin granules, is surrounded by a thin layer of cytoplasm. The cytoplasm on one side of the nucleus appears to be denser and very often it is possible to make out a few darkly staining granules in this area. These are the Golgi bodies and they lie aggregated in a juxta-nuclear mass (Pl. II, Figs. 39 and 40).

Spermatocytes

The resting primary spermatocytes are definitely larger cells than the spermatogonia, their nuclei also being larger (Pl. II, Fig. 41). In the cyto-

plasm there is a juxta-nuclear mass of closely packed dark granules, which are the Golgi bodies.

Each resting secondary spermatocyte is similar to the primary, but it is definitely smaller than the latter (Pl. II, Fig. 42). The nucleus contains inside it a deeply staining nucleolus-like body. The Golgi granules are still lying in a juxta-nuclear mass, but now they are not so closely packed, so that many Golgi granules of various sizes can be made out.

It is notable that the mitochondria are conspicuous by their absence even in the early stages.

Discussion

Undoubtedly the most remarkable feature of the process of sperm formation in *Sympetrum hypomelas* is the complete absence of mitochondrial material right from the earliest spermatogonia to the ripe sperm. On the contrary a prominent Golgi body is formed in the maturing spermatid by the fusion of a few discrete Golgi elements. This Golgi body is directly transformed into a triangular acrosome, which invariably shows a tiny granule perched at the apex of the triangle.

In a recent publication Nath and Bhatia (1953) have reported the complete paling off of the mitochondrial nebenkern of the sperm of *Lepisma domestica*. The mitochondrial nebenkern in this insect is formed in a typical manner, and as is usual in insect spermatogenesis, it consists in the early spermatids of a central chromophilic mass and an outer chromophobic cortex. But, surprisingly enough, the mitochondrial nebenkern does not develop further. On the contrary, it begins to pale off, and is transformed into a pale, fusiform, hyaline structure, which places itself on the surface of the nucleus with the centrosome at its anterior end and the acrosome at its posterior end!! Gradually the mitochondrial nebenkern completely disappears from view and does not contribute at all to the formation of the cytoplasmic sheath of the axial filament of the ripe sperm.

But in the sperm of *Sympetrum hypomelas* the climax is reached inasmuch as the mitochondrial material is never differentiated at all—not to talk of the formation of a mitochondrial nebenkern.

The complete absence of the mitochondrial material in the sperm of *Sympetrum hypomelas* leads us to the conclusion that this material is not essential in the final make-up of the sperm.

In the sperm of the spider *Plexipus paykulli*, as described by Sharma (1950), the mitochondrial material is completely sloughed off. Indeed in this spider Sharma has reported that the nucleus and the axial filament completely wriggle out of the cytoplasm of the cell, which contains the entire mitochondrial content.

A complete absence of mitochondrial material has also been described from the egg of *Culex fatigans* by Nath (1929).

These facts fit into the theory of Hirsch (1939), according to whom there is a primordial lipoidal material in all undifferentiated cells, and gradually with the differentiation of the cell the mitochondria and the Golgi elements, which are allied substances, are differentiated from the

primordial substance. It is, therefore, not surprising if in some cases the primordial lipoidal substance is differentiated into the Golgi elements only.

Another remarkable feature of the sperm of *Sympetrum hypomelas* is the ridiculously small size of the tail of the sperm. This small size is directly related to the fact that the axial filament never emerges out of the cytoplasm of the maturing spermatid.

Lastly there can be no doubt that the acrosome in the sperm of *Sympetrum hypomelas* is formed directly from the Golgi material as described by Nath in several cases of spermatogenesis.

It will be recalled that in the sperm of *Sympetrum hypomelas* we have reported an intra-nuclear rod and two darkly staining areas, one at the anterior and the other at the posterior end of the nucleus. We propose to defer a detailed consideration of these structures to a later stage, when we have completed our observations on the living material under the Phase Contrast Microscope.

Summary

1. The spermateleosis of *Sympetrum hypomelas* has been worked out.

2. In the early spermatids the Golgi bodies are in the form of discrete granules, and in later stages they fuse together to form a prominent, spherical Golgi body. This Golgi body directly forms the acrosome. A prominent granule is invariably seen at the apex of the triangular acrosome.

3. The axial filament of the maturing spermatid never emerges out of the cytoplasm of the cell, with the result that the sperm tail is ridiculously small as compared with the sperm nucleus.

4. In the elongating nucleus of the sperm a vacuolized condition of the ground substance can be observed in suitably differentiated cells.

5. A prominent intra-nuclear rod can be observed in the over-differentiated ripening sperms.

6. Mitochondria are conspicuous by their absence throughout spermatogenesis.

7. In the spermatogonia and spermatocytes the Golgi elements are in the form of granules and are arranged in a mass on one side of the nucleus.

Explanation of Plates

All the figures have been drawn with camera lucida at the table level with Spencer 10 × eyepiece using an oil immersion objective. They are subsequently enlarged two times, thus giving an approximate total magnification of 3,400 times. Figures 3 to 12 and 39 to 42 have been selected from the sectioned material fixed in Flemming-without-acetic acid followed by 0·5% iron haematoxylin. All the others have been drawn from smears fixed in Flemming-without-acetic acid, diluted with an equal quantity of distilled water and stained with 0·5% iron-haematoxylin.

Lettering

A—Acrosome; *AF*—Axial filament; *C*—Centrosome; *Chr*—Chromatin; *Cs*—Cytoplasmic sheath; *G*—Golgi body; *I*—Intra-nuclear rod; *N*—Nucleus; *Nu*—Nucleolus; *R*—Remnant; *T*—Tail.

THE LOUSE SPERM

By G. P. Sharma *and* A. P. Malik, *Department of Zoology, Panjab University College, Hoshiarpur*

Introduction

Sharma (1944) referred to the work on the louse sperm, carried out by Daljit Singh Sarkaria in the Zoological laboratories of the Government College, Lahore (now in Pakistan). Sarkaria worked out fully the spermatogenesis of the cattle-louse, *Haematopinus tuberculatus*, obtained from buffaloes of Lahore and published the results of his investigations in the form of a short abstract in the Proceedings of the 31st Indian Science Congress held at Delhi in 1944. In this communication he confirmed the earlier work of Doncaster and Cannon (1920) on the spermatogenesis of the louse (*Pediculus corporis* and *Pediculus capitis*). He could not, however, publish a detailed account of his investigations as the manuscript and the slides prepared by him were all left in Lahore and could not be brought to this side of the border on account of the partition of the country. Consequently one of us (A. P. M.), at the suggestion of Prof. Dr. Vishwa Nath, prepared some slides of the testicular material obtained from the two species of louse, viz., *Pediculus capitis* and *Pediculus corporis* and these were studied independently as well as jointly by both of us. The present paper is an account of these studies.

Previous Work

Although the spermatogenesis in insects has been the subject of investigation for a number of years, yet we find very few papers dealing with the sperm of louse. The reason for this seems to be the very small size of the germ cells in all the lice examined so far by the various workers.

The earliest work on the sperm of louse is that of Foot (1919), who worked out the spermatogenesis of *Pediculus vestimenti*. According to her the number of chromosomes in the somatic as well as the spermatogonial cells is ten. She also noticed an unequal bivalent in the primary spermatocytes. Although the division of the secondary spermatocytes was not observed by her, yet she assumed that this division was similar to that in corresponding mitoses in the other species of Hemiptera. Strange as it would appear, Foot has not mentioned or figured so conspicuous a structure as the mitochondrial nebenkern in her paper.

Doncaster and Cannon (1920) also worked out the spermatogenesis of two species of *Pediculus*, viz., *corporis* and *capitis* and noted some very interesting facts about the sperm formation in these lice. According to them the somatic number of chromosomes is twelve but the spermatogonial division stages show only six. This haploid number of chromosomes at

the spermatogonial stage has been ascribed by them to premature pairing. They further state that in *Pediculus* only one maturation division is met with and that too is very unequal so far as the cytoplasmic components are concerned. A small nucleus with a little amount of cytoplasm is nipped off from the relatively very large cell which retains the most of the cytoplasm, the whole of the mitochondrial nebenkern and the acroblast. Doncaster and Cannon were, however, not sure of the origin and nature of the acroblast but they rightly suspected that it belonged to the category of the Golgi apparatus. They have also demonstrated very clearly that the acroblast is directly transformed into the acrosome. The spermatid, according to them, has two centrosomes and from each an axial filament is given out. The mitochondrial nebenkern (their mitosome) has been shown by them to have a plate-work structure.

Doncaster and Cannon (1920) make no reference to Foot (1919) as they had not seen her paper. Later on, however, when Cannon studied this paper and found her account differing so much from the one given by Doncaster and himself he decided to make a thorough examination of the testicular material of three more species of louse, viz., *Lignognathus piliferus, Haematopinus asini* and *Haematopinus consobrinus*. As a result of these fresh investigations Cannon (1922) published another paper in which he not only criticized Foot (1919) but also confirmed the earlier account of spermatogenesis given by Doncaster and himself for the two species of louse, viz., *Pediculus corporis* and *Pediculus capitis*.

Material and Method

Both the species of the genus *Pediculus*, viz., *capitis* (the head louse) and *corporis* (the body louse) are found in abundance on a person with unclean habits. The head lice are found mostly on the scalp, clinging to the roots of the hair. The body lice, on the other hand, may be found on the skin of those parts of the body which are covered over with clothes, but a great majority of them are seen hiding in the seams of the inner clothing.

In the young stages, when the external sexual characters are not developed, the male lice cannot be distinguished externally from the females. However, the testes in these very young and small lice are very well developed while the ovaries in the females of the corresponding stages are not so.

For fixing the testes a live louse is first placed in a drop of saline water on a slide under a mounted lens. The thorax is held in position by means of a needle with one hand and the tip of the abdomen is cut with the other, using a sharp scalpel or another needle. The contents of the abdomen are then squeezed out by slight pressure and the testes, which are in the form of white pear-shaped bodies, can be easily spotted. There are two pairs of these pear-shaped bodies, a pair situated on each side. In each pair the two pear-shaped structures are placed with their broader ends facing each other. From the broad inner end of each lobe of the testis is given off a vas deferens. The two vasa deferentia soon unite to form a common vas

deferens on each side. It is always better to take out the testes along with the vasa deferentia as, by doing so, it becomes easier to handle them during the later processes of fixation, washing, dehydration and embedding, etc.

Out of the several fixatives tried, Champy's and Flemming's—without acetic acid—gave the best results so far as the cytoplasmic inclusions are concerned. Flemming's—without acetic acid—was used with various modifications, but with 75% of water it gave excellent revelations of the Golgi apparatus and the mitochondria.

The material fixed in Flemming's and in Bouin's fluid particularly, gave us the best preparations for the study of the chromatin contents especially during the division stages. The presence of the two centrosomes and the two axial filaments in the spermatid was also confirmed by sections obtained from the material fixed in Bouin's fluid.

The sections were mordanted in 4% iron alum, stained in 0·5% haematoxylin, differentiated in 2% iron alum, dehydrated as usual and were mounted finally in Canada balsam.

Observations

Spermatogonia

In both the species of the genus *Pediculus*, viz., *capitis* and *corporis* the spermatogonia fill up practically the whole of the space in the testes of a younger louse. As the louse, however, matures the spermatogonia occupy lesser and lesser space and ultimately become confined only to the distal narrow ends of the testes and a little way down along the sides of the testes.

The spermatogonia are small and round cells, when lying free, but they may appear as many as five- or six-sided, when seen in a compact follicle.

Each spermatogonium has a comparatively large nucleus, occupying generally a central position. The nucleus invariably contains a big darkly staining nucleolus which is surrounded by a clear area. The nuclear membrane at this stage is not very conspicuous (Plate I, Fig. 1). The cytoplasm in the spermatogonia stains uniformly and does not show any prominent structure like the Golgi apparatus or the mitochondria. The spermatogonial wall is very delicate as is typical of the animal cells.

In the testes of *Pediculus* the division stages of the spermatogonia were rarely seen. The spermatogonia, however, divide a number of times as is evident from the increasing size of the testes which are very much larger in the fully grown animal but are still filled up with spermatogonial cells only. When a spermatogonium prepares to divide the first structure to appear in its cytoplasm is the centrosome in the form of a small granule which soon divides into two (Plate I, Fig. 2). The nuclear membrane round the clear area of the nucleus also becomes prominent at this stage. Small chromatin granules or prochromosomes now make their appearance and they arrange themselves on the inside of the nuclear membrane (Plate I, Figs. 3, 4 and 5). These prochromosomes gradually grow larger and finally obliterate the entire clear space inside the nucleus. The nuclear membrane at this stage is very prominent (Plate I, Fig. 6). Most of these

prochromosomal granules are double from the very beginning and the maximum number of chromosomes during the present studies has been found to be six. With the growth of the prochromosomes the nucleolus becomes less prominent and finally disintegrates completely, probably contributing to the formation of the chromosomes. During the metaphase stage of the spermatogonial divisions the chromosomes arrange themselves in the form of a ring on the equator of the spindle and their double structure can be clearly seen in the polar as well as the sideviews of the spermatogonial spindles (Plate I, Figs. 7 and 8). Each spermatogonial spindle is a fusiform area completely devoid of any fibrillar structure. At each pole of the spindle is a conspicuous darkly staining centrosome which is also devoid of astral rays.

Spermatocytes

In *Pediculus corporis* the mitochondria put in their appearance for the first time just when the growth phase begins in the spermatocytes (Plate I, Figs. 9 to 11). In *Pediculus capitis*, however, they appear at a little later stage of growth in the spermatocytes (Plate I, Fig. 12). In the former case, the mitochondria, to begin with, occupy the whole of the cytoplasmic space available around the nucleus (Plate I, Fig. 9) while in the latter they are seen lying scattered loosely on one side of the nucleus (Plate I, Fig. 12). The mitochondria, at the time of their first appearance, are in the form of granules but due to their very small size and their readiness to take up the stain intensely it often becomes difficult to demonstrate their exact structure.

Like the spermatogonia each spermatocyte also possesses a nucleus with a very prominent nucleolus which is surrounded by a clear space and a very faint nuclear membrane. The spermatocyte may grow as much as about four times the size of a spermatogonium. With its growth the mitochondria tend to collect together in one half, while the nucleus occupies the other half of the spermatocyte (Plate I, Figs. 12 and 13). At this stage the mitochondrial granules may be arranged in a number of ways. They may be lying either in the form of one compact mass, or in a semi-circle or in the form of a complete ring (Plate I, Fig. 13).

The small mitochondrial granules gradually fuse with each other to form bigger and fewer granules. These may now be termed as the mitochondrial vesicles because each one of them seems to be made up of a chromophilic cortex and a chromophobic core (Plate I, Fig. 14). Later on, however, these mitochondrial vesicles lose their identity as such and this results from their further fusion with each other. The mitochondrial mass, which may now be called the mitochondrial nebenkern, appears at this stage in the form of an anastomosing network (Plate I, Fig. 15). This reticulate formation seems to be made up of the chromophilic portion of the mitochondrial vesicles while the spaces in it are filled up with the chromophobic material. This mitochondrial mesh-work has larger chromophobic spaces near its periphery than in the centre (Plate I, Fig. 15). As the condensation of the mitochondrial nebenkern proceeds further the chromophilic mass is gradually withdrawn from the peripheral portion

of the reticulum till we get a few large chromophobic cavities which are still provided with thick chromophilic walls surrounding the central chromophilic mass in a more or less irregular fashion (Plate I, Fig. 16). Most of the chromophilic material from the walls of the peripheral chromophobic cavities is further retracted centrally with the result that they become perfectly chromophobic except for the thin chromophilic rims only (Plate I, Figs. 17 and 18, and Plate II, Fig. 19). In properly differentiated sections the central chromophilic area always shows a number of lines traversing it. These mark the boundaries of the alveoli which are still present in this area. If, however, the stain is not properly extracted the central chromophilic mass appears structureless. Later on the number of alveoli in the central chromophilic mass is gradually reduced till only a few lines can be seen traversing this area (Plate I, Fig. 18, and Plate II, Fig. 19). We have now reached a stage in which the mitochondrial nebenkern possesses a few prominent peripheral chromophobic cavities surrounding a central chromophilic mass.

During all the above-mentioned changes in the mitochondrial material i.e., from the small mitochondrial granules to a star-shaped mitochondrial nebenkern (Plate I, Figs. 9 to 18, and Plate II, Fig. 19) the spermatocytes do not exhibit any other structure beside it, except the nucleus with a prominent nucleolus which is surrounded by a clear area.

In *Pediculus capitis*, further differentiation of the mitochondrial nebenkern in the spermatocyte leads to the formation of a very beautiful pattern. In an optical section this looks something like a set of four rings of different sizes, made up of the chromophilic material (Plate II, Figs. 20 to 23). This mitochondrial nebenkern appears differently in different sections, the shape depending on the angle a section is cut. The chromophobic material still surrounds the chromophilic rings of the mitochondrial nebenkern and also fills up the spaces enclosed by the various rings. In reality these rings are thick-walled shells which are made up of the chromophilic material. One of them is larger than the others which are invariably enveloped by it (Plate II, Fig. 23). In all these stages the mitochondrial nebenkern occupies a central position in the cell, while the nucleus is pushed towards one side (Plate II, Figs. 20 to 23).

Before the division of the spermatocyte a number of characteristic changes take place in the cell. Firstly the chromophilic portion of the mitochondrial nebenkern fades away gradually, with the result that only a shaded outline marks its existence during meiosis. The chromophobic substance, however, still envelops the very lightly but uniformly stained chromophilic portion of the mitochondrial nebenkern, separating it from the rest of the cytoplasm (Plate II, Figs. 24 to 28).

Secondly there appears for the first time a darkly staining and perfectly spherical structure, about the size of the nucleolus, in the cytoplasm of the spermatocyte. This is the Golgi body which could not be observed in any of the earlier stages of spermatogenesis (Plate II, Figs. 24 to 28).

In all these pre-division stages of the spermatocytes the nucleolus is the only structure which can be made out in the nucleus. But a few small

granules, known as the prochromosomes, now put in their appearance just underneath the nuclear membrane (Plate II, Fig. 24). The nucleolus also soon disappears probably contributing to the growing chromosomes (Plate II, Fig. 25). These chromosomes are clearly double even when they are in the making. Figures 26 and 27, in Plate II, depict the anaphase stages of the spermatocyte division in which the chromosomes have moved quite apart on the spindle but the mitochondrial nebenkern and the Golgi body show no signs of division.

The meiotic spindle, like the one seen during spermatogonial mitosis, is a fusiform area completely devoid of any fibrillar structure. At each pole of the spindle, there is a conspicuous darkly staining centrosome which again is devoid of astral rays. Corresponding to the position of the nucleus in the early stages of the spermatocytes the spindle also lies eccentrically in the cell throughout the meiotic division.

In figure 28, Plate II, is shown a late telophase stage of the meiosis in which the two sets of chromosomes have already given rise to two daughter nuclei. One of these nuclei is seen lying in a finger-like outgrowth of the dividing cell, while the main body of the cell has retained not only the other nucleus but also the whole of the mitochondrial nebenkern and the Golgi body. This spermatocyte division is thus extremely unequal so far as the cytoplasm and its inclusions are concerned. The smaller cell containing one of the daughter nuclei and a little amount of cytoplasm gets cut off from the main body of the cell just like a polar body from a maturing ovum. This small cell does not undergo any further development as it is very often seen as such, lying along with the maturing spermatids (Plate III, Fig. 33).

There has not been observed any other division of the spermatocyte.

Spermateleosis

Even in the earliest spermatids of both the species, viz., *Pediculus capitis* and *Pediculus corporis* we find two centrosomes lying in close proximity to the nucleus (Plate II, Figs. 29 and 30). This fact clearly proves that the originally single centrosome soon divides into two in preparation for the second meiotic division which, however, does not take place due to some unknown reasons. The nucleus has resumed its shape which is so typical of the resting stages, i.e., there is only a small nucleolus with a clear space around it.

After the meiosis, the next change that the mitochondrial nebenkern undergoes in the spermatid, is characterized by the appearance of a new chromophilic mass in place of the previous chromophilic material of the mitochondrial nebenkern. This new substance is in the form of big vesicles but differs from the old chromophilic material in being not so deeply stainable (Plate II, Figs. 29 and 30). This new chromophilic substance corresponds to the 'Central substance' of Bowen (1922) or 'sheath substance' of Nath (1925) as it ultimately forms the sheath of the tail of the ripe sperm. The number of vesicles observed in the newly appeared 'sheath substance' is quite large in the beginning (Plate II, Fig. 29), but later on these vesicles seem to coalesce with each other gradually till only

one big spherical structure is formed (Plate II, Fig. 31, and Plate III, Fig. 32). In sections of the late spermatids the 'sheath substance' appears in the form of a ring of chromophilic material enclosing a chromophobic substance inside. The latter substance also completely envelops the chromophilic sphere, separating it from the rest of the cytoplasm.

An axial filament now grows out from each of the two centrosomes lying beneath the nucleus. Considering the nuclear end of the spermatid as the anterior, the two axial filaments grow backwards towards the posterior end of the cell (Plate II, Fig. 31). In some such cells one of the two axial filaments appears to divide the mitochondrial nebenkern into two symmetrical halves (Plate III, Figs. 33 and 37). The other axial filament seems to be a bit thicker than it but as it lies in close proximity to the mitochondrial nebenkern it is not always possible to discern it.

The growing axial filaments sometimes protrude a little out of the cell at the posterior end, carrying at their free outer ends small knob-like distal centrosomes. These resemble very much the antennæ of a butterfly (Plate III, Fig. 32). But that is not the end, because the axial filaments still grow further, carrying a little amount of cytoplasm along with them, till they attain a length which is roughly double that of the cell they are lying in (Plate II, Fig. 31). The two axial filaments very often get twisted over each other outside the main body of the cell.

The single spherical Golgi body may be lying anywhere in the cytoplasm in the early stages of spermateleosis (Plate III, Fig. 33), but mostly it is found in the anterior region of the cell. As the spermatid begins to elongate the Golgi body comes to lie very near the posterior end of the nucleus, quite often overlapping one of the centrosomes (Plate II, Fig. 31, and Plate III, Figs. 32 and 35 to 37).

In the elongating spermatids the nucleolus disappears and the nucleus becomes solid, the whole of it getting packed up with the deeply staining chromatin contents (Plate III, Figs. 32 and 33).

As regards the elongation of the spermatids a slight difference has been noted between the two species. In *Pediculus corporis* the head region of the spermatid, consisting of the nucleus, Golgi body, centrosomes and a little cytoplasm takes a lead in the process of elongation. This region is pushed out like a small bulb-like off-shoot from the main body of the cell and remains connected with it by means of a broad neck (Plate III, Fig. 35). In *Pediculus capitis*, on the other hand, the process of elongation is accomplished rather uniformly. As is shown in Figures 36 and 37, Plate III, the cell is narrowed down as a whole with the cytoplasm preceding the nucleus and the other structures anteriorly.

Next and the most important step in spermateleosis is the movement of the Golgi body from the posterior to the anterior end of the nucleus. This process is clearly illustrated in Figures 39 to 42, Plate III. As has already been said the Golgi body is generally found near the nucleus in the elongating spermatids. Later on it gets applied to the posterior end of the nucleus (Plate III, Fig. 32) over which it spreads like a cap on one side of it (Plate III, Figs. 39 to 41). Finally the whole of the substance of the Golgi body, after having crept over the nuclear membrane is accumulated

in front of the nucleus (Plate III, Figs. 42 to 44). This spherical Golgi body, now lying at the anterior end of the nucleus, is practically of the same size as at the time when it started its journey over the nuclear membrane. It is, therefore, quite clear that no part of the Golgi body is left behind or cast off. For some time now the lengthening of this Golgi body to form the acrosome is postponed till the nucleus has elongated considerably.

It has been mentioned before that the nucleus in the early stages of spermateleosis takes up a uniform and intense stain. But when the Golgi body starts moving up along one side of the nucleus its staining capacity is once again lost. At this stage the nucleus is generally quite clear (Plate III, Figs. 39 to 42) but sometimes it reveals inside it a deeply staining nucleolus-like body which is so characteristic of the early stages of spermatogenesis (Plate III, Fig. 38).

The nucleus which has so far been almost perfectly spherical now begins to elongate, carrying at its tip the button-like Golgi body. As a result of this elongation the nucleus may attain a length which is approximately three or four times its original diameter (Plate III, Figs. 43 and 44).

With the narrowing of the spermatid, the centrosomes come to lie so close to each other as to look like one whole mass and the same is the case with the axial filaments. When the spermatids have spun out considerably the separate entity of the axial filaments cannot be made out (Plate III, Figs. 43 and 44).

The middle portion of the spermatid thins out comparatively sooner than the anterior and the posterior regions with the result that the bulk of the 'sheath substance' gets accumulated in the posterior region which appears as a spindle-shaped swelling (Plate III, Fig. 43).

After this the cell attenuates enormously. The head consisting of the nucleus behind and the Golgi body in front tapers anteriorly from its comparatively broad base. Like the nucleus the Golgi body also spins out anteriorly to form a long flagellum-like acrosome (Plate III, Fig. 45). With further elongation of the cell, the spindle-shaped swelling in the tail region disappears as it seems to spread out uniformly along the whole length of the sperm tail. Consequently the discrimination between the two substances, i.e., the cytoplasm and the 'sheath substance' of which the spindle-shaped swelling is made, is done away with in the mature sperm.

Discussion

(a) *Golgi apparatus and Acrosome*

Doncaster and Cannon (1920) state that in *Pediculus* the acroblast, which is really the Golgi apparatus, may 'sometimes be double at the time of its first appearance, but is always a single spherical body later'. Similarly in the horse-louse, *Haematopinus asini*, Cannon (1922) records that the acroblast 'is usually, but not always, double and remains so until the spermatid has formed and is elongated'. On the other hand, in the two species of *Pediculus*, viz., *capitis* and *corporis*, investigated by us, the Golgi apparatus, from the very beginning, is in the form of a single, spherical

and darkly staining body. It appears for the first time in the cytoplasm of the spermatocyte. It could not be observed in the spermatogonia and in the spermatocyte too it appeared quite late, just at the time when the nucleus had started preparing for the division. It takes up the haematoxylin stain rather sharply and homogeneously. In good preparations its outline is always evenly circular and it is generally surrounded by a small lightly staining cytoplasmic area. In size it is equal to that of the nucleolus of the resting stages. Doncaster and Cannon (1920) and Cannon (1922) were doubtful about the origin and nature of the acroblast but judged from the roll that it plays in the formation of the acrosome there seems to be no doubt at all about its original nature that it belongs to the category of the Golgi apparatus. Actually in Mann-Kopsch preparations of the dog-louse, *Lignognathus piliferus* there are, according to Cannon himself (1922), indications of the acroblast arising from two or three scattered granules which may be the true Golgi bodies.

From its first appearance to the time till it forms an acrosome there takes place no change of any kind in the single spherical Golgi body. In other words it remains as such during the only maturation division and goes as a whole to one daughter cell only. In the earliest spermatid, thus formed, the Golgi body may be lying anywhere in the cytoplasm. In the late spermatids, however, it shows a distinct tendency to be near the nuclear or the anterior end. As the spinning out process to form the ripe sperm is taking place the Golgi body comes to lie very close to the nucleus and gets applied to its membrane at the posterior end. It then begins to creep over the surface of the nucleus and in doing so it forms a sort of cap over its one side. Gradually the whole of the substance of the Golgi body, after having crept over the nuclear membrane, is accumulated in front of the nucleus. The size of this Golgi body, now lying at the anterior end of the nucleus, is practically the same as at the time when it started its journey over the nuclear membrane. It is, therefore, quite clear that no fragment of the Golgi body is left behind or cast off. Some similar observations have been made by Doncaster and Cannon (1920) on *Pediculus*. But in the horse-louse, *Haematopinus asini* Cannon (1922) records 'that during spermateleosis the double acroblast loses one of its halves, which passes away from the nucleus and disappears'. This apparently useless half of the acroblast can be easily homologized with the Golgi remnant recorded in so many animals.

Further development of the Golgi body takes place only after the nucleus has elongated considerably. Then by a spinning out process the Golgi body is transformed directly into a long flagellum-like acrosome which is narrower in front and a little broad behind. This whole structure gets so much blended in general appearance with the likewise elongated nucleus that in the mature sperm it becomes increasingly difficult to discriminate one from the other.

These observations regarding the direct origin of the acrosome from a single spherical Golgi body completely confirm the earlier accounts of Doncaster and Cannon (1920) and Cannon (1922). Recently in this laboratory Nath and Bhatia (1953) have also clearly shown that in *Lepisma*

the acrosome is formed by the direct fusion of the Golgi vesicles and is not a secretory product thereof, as described by Bowen (1924). For the direct origin of the acrosome from the Golgi bodies reference may also be made to Sharma (1944 and 1950) and Nath (1932 and 1942).

(*b*) *Mitochondria*

According to Cannon (1922) the cytoplasm in the earliest spermatogonia of the dog-louse, *Lignognathus piliferus* is completely filled up with vacuolated mitochondria. In *Pediculus*, however, Doncaster and Cannon (1920) were of the opinion that some of the earliest spermatogonia showed granular mitochondria. In contrast to these observations the mitochondria could not be demonstrated at all in the spermatogonia of both the species of *Pediculus*, viz., *capitis* and *corporis* investigated by us. They appear for the first time in the spermatocytes at a time when the growth phase has started. As there is a very large number of these mitochondria, to begin with, they just look like a black cloud in an overstained preparation. But in a carefully differentiated cell each mitochondrium appears as a small granule, which takes up the haematoxylin stain intensely. These mitochondrial granules have a distinct tendency to come together and consequently bigger mitochondrial granules, which are fewer in number, are formed. These may now be termed as mitochondrial vesicles because each one of them seems to have, at this stage, a chromophilic cortex and a chromophobic core. By the running together of these mitochondrial vesicles, is formed a rather compact mitochondrial nebenkern which generally gives an impression of soap bubbles or of an anastomosing network, if there is a lot of stain on it.

The next step in the process of condensation of the mitochondrial nebenkern is that the most of the chromophilic material from the alveoli lying at the periphery is progressively withdrawn, with the result that an irregular envelope of large chromophobic alveoli surrounding a central darkly staining chromophilic mass is formed. In properly differentiated sections the central chromophilic area always reveals a number of lines traversing it and these represent the boundaries of the alveoli which are included in this area. If, however, the stain is not properly removed the central chromophilic mass appears structureless.

With further retraction of the chromophilic substance towards the centre of the mitochondrial nebenkern there are formed a few very large alveoli at its periphery, each with a large chromophobic area enclosed by only a thin chromophilic wall. At this stage the central chromophilic mass of the mitochondrial nebenkern clearly reveals a plate-work structure as shown earlier by Doncaster and Cannon (1920) and Cannon (1922) and not a spireme as urged by Gatenby (1917). This plate-work consists of a number of spherical or ovoid shells with thick walls of a chromophilic material and containing in them a chromophobic substance. These shells are of different sizes and the biggest of them seems to envelop all the others. In optical sections these shells appear as rings which look different in different views, depending upon the angle a cell is cut. The maximum number of these rings, observed in a section, is four.

As the spermatocyte prepares for the only meiotic division the central chromophilic part of the mitochondrial nebenkern gradually grows dim and ultimately fades away altogether. Consequently only a lightly staining sphere, surrounded by a clear area, marks the existence of the mitochondrial nebenkern during the division stages. Doncaster and Cannon (1920) have also clearly shown in their figures this fading away of the chromophilic part of the mitochondrial nebenkern but they make no reference to it in their text. In their explanation of plate, however, they mention in the form of a note that the acroblast (our spherical Golgi body) and the mitochondrial body (our mitochondrial nebenkern) are not preserved in their figures 11 to 13 which depict the division stages of the spermatocyte.

The mitochondrial nebenkern does not divide at all during the spermatocytic division but, like the Golgi body, it is simply passed on as such to one of the two daughter cells only.

In the spermatid the mitochondrial nebenkern is always lying almost in the centre of the cell, the two centrosomes lying between it and the nucleus. A new chromophilic substance now makes its appearance in place of the old one. This new substance in the central part of the mitochondrial nebenkern differs from the old chromophilic material inasmuch as it does not take up the haematoxylin stain intensely. In this paper it has been homologized by us to the 'central substance' of Bowen (1922) or the 'sheath substance' of Nath (1925) as it ultimately forms the sheath of the tail of the ripe sperm. The number of vesicles observed in this newly appeared 'sheath substance' is quite large, to begin with, but later on these vesicles seem to coalesce with each other gradually, till only one big spherical structure is formed. In sections of the late spermatids the 'sheath substance' appears in the form of a ring of chromophilic material enclosing a chromophobic substance inside. The latter substance also envelops it completely from all sides, separating it from the rest of the cytoplasm.

When the axial filaments start growing out, the mitochondrial nebenkern appears to be divided into two equal halves by the impressing of one of the axial filaments on the envelope of this body. The symmetrical disposition of the two parts can be clearly made out in the cross-sections of the spermatids at this stage.

As the spinning out of the spermatid takes place during the process of sperm formation the mitochondrial nebenkern is also drawn out along with the cytoplasm. In the penultimate stage the bulk of the sheath-forming substance of the mitochondrial nebenkern gets accumulated in a swelling in the posterior region of the attenuated spermatid. Finally, however, when the sperm has drawn out to its full length, the sheath-forming substance of the mitochondrial nebenkern is also spread out uniformly, forming the sheath of the tail of the ripe sperm.

It will thus be seen from the foregoing account that a mitochondrial nebenkern which is so typical of the insect spermatogenesis is also formed in the two lice examined by us by the usual process of running together of the mitochondrial vesicles. The only difference is that in the lice the

process of condensation of the mitochondrial nebenkern starts as early as in the spermatocyte and not in the spermatid as in the other insects.

(*c*) *Nucleus*

In the spermatogonia of both the species of *Pediculus*, viz., *capitis* and *corporis* the nucleus is the only structure to be found besides comparatively little cytoplasm in which it is placed almost in the centre. In the resting stages of both the spermatogonia and the spermatocytes the nucleus always reveals a prominent darkly staining nucleolus surrounded by a clear area and a very faint nuclear membrane. The spermatocyte nucleus is almost of the same size as that of the spermatogonium, but it now lies towards one side of the cell and is not situated in the centre as was the case in the spermatogonia. In both the spermatogonia and the spermatocytes the nuclear membrane becomes conspicuous only when the nucleus is preparing for the division.

Just before each division, whether mitotic or meiotic, small prochromosomal granules appear in the clear space around the nucleolus. The latter, however, disappears, probably contributing to the growing chromosomes which finally fill up the whole of the available space in the nucleus. In *Pediculus* there is not formed in the nucleus any structure like a spireme. In the dividing spermatocyte, corresponding to the position of the nucleus in the resting stages, the meiotic spindle also lies eccentrically in the cell.

Another interesting fact about *Pediculus* is that unlike the normal state of affairs during meiosis, the division of the nucleus fails to induce the other cell components to divide into two parts. The result is that one small daughter nucleus along with a little amount of cytoplasm is nipped off from the main cell which retains not only the single spherical Golgi body but also the whole of the mitochondrial nebenkern. The small polar-body-like cell does not undergo any further development. A similar single spermatocyte division has also been observed by Meves (1907) and Mark and Copeland (1906) in the hive-bee.

After this only meiotic division the nucleus in the early spermatid resumes its normal shape, typical of the resting stages, but with this difference that it is now considerably smaller. As the spermatid begins to elongate the chromatin gets distributed evenly throughout the clear space in the nucleus which now stains intensely and uniformly. In the late stages of spermatcleosis, however, when the single spherical Golgi body is moving towards the anterior side along one side of the nucleus, it loses its staining capacity and becomes clear once again. In some such cells a deeply staining nucleolus-like body was also seen in the centre of the nucleus but it disappeared quickly. On the other hand, Doncaster and Cannon (1920) have described a deeply stained oval body which lies within the nucleus at the posterior end of more elongated heads and this seems to persist till the formation of the ripe sperm.

During the transformation of the spermatid into the sperm the spherical nucleus of the earlier stages is lengthened out along a line continuous with the axis of the tail sheath. As a result of this, the nucleus

thins out anteriorly leaving its posterior region comparatively broad. This elongated nucleus carries at its tip the spherical Golgi body which is also now spun out directly into a long flagellum-like acrosome. The elongated nucleus and the acrosome together at this stage form a needle-like head for the ripe sperm.

(*d*) *Centrosomes and Axial filaments*

In both the species of *Pediculus*, viz., *capitis* and *corporis* the centrosome is not visible during the resting stages of the spermatogonia and the spermatocytes. When a spermatogonium prepares to divide the centrosome is the first new structure to put in its appearance in the cytoplasm of the cell and it soon divides into two. This structure is very conspicuous in the preparations made from the material fixed in Bouin's fluid but it could not be made out with certainty in the sections of the material fixed in Flemming's—without acetic acid. During the division stages of both the spermatogonia and the spermatocytes the centrosomes behave as usual, i.e., they are found at the apices of the spindle as darkly staining granules. They have neither the astral rays nor any clear area round them.

The spindle, whether it is mitotic or meiotic, is a fusiform area completely devoid of any fibrillar structure. The characteristic feature of the meiotic spindle is that throughout the division period it remains lying quite eccentrically in the cell.

Even in the earliest spermatid there are found two centrosomes. It is, therefore, quite evident that the originally single centrosome divides immediately into two preparatory to the second maturation division of the spermatocyte which, however, does not take place in *Pediculus* due to some unknown reasons.

The two centrosomes in the spermatid are always lying beneath the nucleus in close proximity to it. Later an axial filament grows out from each centrosome and proceeds to the posterior side. These growing axial filaments may sometimes be seen to bear at their free ends the distal centrosomes. The two axial filaments grow extensively and outside the cell they get twisted round each other. One of the axial filaments appears to divide the mitochondrial nebenkern into two symmetrical halves and the other seems to be a bit thicker than it.

In some of the elongating spermatids one of the centrosomes is lost to view as it becomes covered over by the single spherical Golgi body which now takes its position at the posterior end of the nucleus to make its forward journey along one side of the nucleus. In the late stages of spermateleosis the two centrosomes come to lie so near each other that their separate entities cannot be made out. Similarly the two axial filaments also appear as one at this stage.

Doncaster and Cannon (1920) have also described a double centrosome and two axial filaments in the elongating spermatids. They are quite definite that both the axial filaments pass outside the mitochondrial nebenkern. According to them the bilateral symmetry of the mitochondrial nebenkern is possibly due to the line of junction of the two outer vacuoles running over its surface. On the other hand, we have clearly

shown that it is due to the impressing of one of the axial filaments upon the envelope of this body. Similar observations have also been made by Gatenby (1917).

Summary

1. In this paper the spermatogenesis of two species of louse, viz., *Pediculus capitis* and *Pediculus corporis* is described.

2. Each spermatogonium contains a large nucleus with a prominent nucleolus in the centre and comparatively very little cytoplasm.

3. The mitochondria appear for the first time in the growing spermatocytes in the form of a dense cloud of numerous small granules. These gradually fuse to form a fewer and bigger granules which may now be termed as the mitochondrial vesicles, each having a chromophilic cortex and a chromophobic core.

4. By the running together of these mitochondrial vesicles, is formed a typical mitochondrial nebenkern the condensation of which starts as early as in the spermatocyte. The structure of the chromophilic part of the mitochondrial nebenkern is that of a plate-work.

5. The Golgi apparatus also appears in the spermatocyte at a time when it is preparing for the division. It is in the form of a single, darkly staining, spherical body.

6. There is only a single spermatocyte division during which the single spherical Golgi body and the whole of the mitochondrial nebenkern are passed on as such to only one daughter cell. The other daughter cell containing a small nucleus and a little amount of cytoplasm degenerates.

7. During the only meiotic division the chromophilic part of the mitochondrial nebenkern disappears and in its place a new chromophilic substance appears in the spermatid. This forms the sheath of the tail of the ripe sperm.

8. During spermateleosis the spherical nucleus attenuates anteriorly leaving its posterior end comparatively broad.

9. The single spherical Golgi body of the early spermatid first moves from the posterior to the anterior end of the nucleus and is later on transformed directly into a long flagellum-like acrosome during the late stages of spermateleosis.

10. There are two centrosomes in the spermatid from the very beginning and from each one of these is given out an axial filament. In the ripe sperm, however, it is as difficult to make out their separate entities as it is to distinguish the acrosome from the nucleus.

Explanation of Lettering in the Plates

A—Acrosome; *Af*—Axial filament; *C*—Centrosome; *Ch*—Chromosomes; *Ch'*—Prochromosomes; *G*—Golgi body; *M*—Mitochondria; *M.n.*—Mitochondrial nebenkern; *N*—Nucleus; *N'*—Nucleolus.

Explanation of Plates

All figures have been drawn with a Spencer Camera lucida at the stage level, using Spencer 10× eyepiece and an oil immersion objective. They were subsequently enlarged 16 times, thus giving a total magnification of 16,000 times. Unless otherwise mentioned in the text all figures have been selected from preparations of *Pediculus capitis*.

Plate I

Fig. 1. Earliest spermatogonium showing only a nucleolus with a clear space around it and a little cytoplasm.

Fig. 2. A spermatogonium in which a double centrosome and a prominent nucleolus are seen.

Figs. 3 to 6. Spermatogonia showing a prominent nuclear membrane. The prochromosomes are becoming larger gradually.

Fig. 7. Polar view of a spermatogonial metaphase.

Fig. 8. Side view of a spermatogonial metaphase.

Figs. 9 to 11. Early spermatocytes showing numerous mitochondrial granules in the cytoplasm.

Figs. 12 and 13. Spermatocytes after the growth period showing mitochondria accumulated in one-half of the cell while the other half is occupied by the nucleus.

Fig. 14. Spermatocyte in which the small mitochondrial granules have fused to form a few big mitochondrial vesicles.

Fig. 15. Spermatocyte in which a network-like structure is formed by the fusion of mitochondrial vesicles.

Figs. 16 to 18. Late spermatocytes showing condensation of the mitochondrial nebenkern.

Plate II

FIGS. 19 to 23. Late spermatocytes showing condensation of the mitochondrial nebenkern.

FIGS. 24 and 25. Spermatocytes preparing for the division, showing faded mitochondrial nebenkern. Prochromosomes are seen developing into the nucleus. The Golgi apparatus has also appeared in these cells in the form of a single spherical body.

FIGS. 26 and 27. Anaphase stages of the only spermatocyte division. The single spherical Golgi body and the faded mitochondrial nebenkern are not dividing.

FIG. 28. Late telophase stage of the only spermatocyte division. One of the daughter nuclei lying in a finger-like outgrowth of the cell.

FIGS. 29 and 30. Early spermatids showing two centrosomes lying underneath the nucleus. The newly appeared 'sheath substance' can also be seen in the mitochondrial nebenkern.

FIG. 31. Elongating spermatid with two long axial filaments forming a tail-like structure.

Plate III

FIG. 32. Spermatid in which the two axial filaments along with their distal centrosomes are seen protruding out of the cell like the antennæ of a butterfly.

FIGS. 33 and 34. Cross-sections of the elongating spermatids through the anterior and posterior regions respectively.

FIGS. 35 to 38. Elongating spermatids.

FIGS. 39 to 42. Anterior ends of the elongating spermatids showing the creeping up of the Golgi body along one side of the nuclear membrane.

FIG. 43. A late spermatid showing a cone-shaped nucleus with a button-like Golgi body situated at its anterior end. The bulk of the sheath-forming substance is accumulated in the spindle-shaped swelling in the tail region.

FIG. 44. A very late spermatid showing the process of attenuation.

FIG. 45. A nearly ripe sperm showing the needle-like acrosome lying in front of the elongating nucleus.

POTENTIOMETRIC STUDIES IN OXIDATION-REDUCTION REACTIONS

Part XVIII. Oxidation with Alkaline Potassium Permanganate

By Balwant Singh, Apar Singh *and* Miss Raj Kumari Nahan

Holluta (*Z. Phys. Chem.*, 1922, **102**, 32 and 276) has shown that in the reaction between permanganate and formate the reduction of permanganate in alkaline solution proceeds in two stages:—

$$MnO_4^- + e = MnO_4^{--} \quad .. \quad .. \quad .. \quad .. \quad .. \quad .. \quad (1)$$

$$MnO_4^{--} + 2\,H_2O + 2e = MnO_2 + 4\,OH^- \quad .. \quad .. \quad .. \quad .. \quad (2)$$

The first of these two reactions proceeds much more rapidly than the second. This is in conformity with the observations of Sackur and Taegener (*Zeit. Elecktrochem.*, 1912, **18**, 718). The difference of the velocities of the two partial reactions increases with rising hydroxyl ion concentration.

According to Stamm's procedure (*Z. angew. chem.*, 1934, **47**, 191; 1935, **48**, 710) the oxidation with alkaline permanganate solution involves only the first partial reaction, i.e., the conversion of permanganate to manganate and the slow conversion of manganate to manganese dioxide is not allowed to occur. To attain the highest possible oxidation velocities, the substance to be determined is added to an excess of alkaline permanganate solution. After the oxidation is finished, the excess of permanganate is titrated back with sodium formate.

$$2\,MnO_4^- + 3\,OH^- + HCO_2^- = 2\,MnO_4^{--} + CO_3^{--} + 2\,H_2O.$$

To prevent the formate from carrying the reduction of the manganate on to manganese dioxide, which would occur as soon as about ninety per cent of the permanganate originally present had changed to manganate, a barium salt is added to the reaction mixture before beginning the addition of the formate. Barium permanganate is soluble in water, while barium manganate is insoluble. The manganate ions produced by the reduction consequently are bound by the barium ions so rapidly that they are effectively removed from any further action of the reducing agent.

P. A. Heredia (*Arch. farm. bioquim. Tucuman*, 1947, 3, 173) found the method of Stamm suitable in the volumetric analysis of potassium iodide, potassium iodate, potassium cyanide, potassium phosphite, methyl alcohol, formaldehyde and formic acid.

In the present investigation alkaline potassium permanganate has been used as an oxidizing agent and the Stamm's procedure employed in the potentiometric estimations of Acetaldehyde, Formaldehyde, Benzaldehyde, Mandelic acid, Cinnamic acid, Tartaric acid, Malic acid, Isoamyl

alcohol, Benzyl alcohol, Ethyl alcohol, *n*-Propyl alcohol, *n*-Butyl alcohol. These compounds *react with alkaline permanganate* according to the following equations:—

1. $2\,MnO_4^- + 3\,OH^- + CH_3CHO = 2\,MnO_4^{--} + CH_3COO^- + 2\,H_2O$
2. $4\,MnO_4^- + 6\,OH^- + H.CHO = 4\,MnO_4^{--} + CO_3^{--} + 4\,H_2O$
3. $2\,MnO_4^- + 3\,OH^- + C_6H_5CHO = 2\,MnO_4^{--} + C_6H_5COO^- + 2\,H_2O$
4. $4\,MnO_4^- + 7\,OH^- + C_6H_5CHOH.COOH$
$= 4\,MnO_4^{--} + CO_3^{--} + C_6H_5COO^- + 5\,H_2O$
5. $10\,MnO_4^- + 15\,OH^- + C_6H_5CH.CH.COOH$
$= 10\,MnO_4^{--} + 2\,CO_3^{--} + C_6H_5COO^- + 9\,H_2O$
6. $8\,MnO_4^- + 14\,OH^- + \begin{vmatrix} CHOH.COOH \\ CHOH.COOH \end{vmatrix}$
$= 8\,MnO_4^{--} + 10\,H_2O + 2\,CO_3^{--} + \begin{vmatrix} COO^{--} \\ COO \end{vmatrix}$
7. $12\,MnO_4^- + 20\,OH^- + COOH.CH_2.CHOH.COOH$
$= 12\,MnO_4^{--} + 4\,CO_3^{--} + 13\,H_3O$
8. $4\,MnO_4^- + 5\,OH^- + (CH_3)_2CH_2CH.CH_2OH$
$= 4\,MnO_4^{--} + (CH_3)_2CH_2.CH..COO^- + 4\,H_2O$
9. $4\,MnO_4^- + 5\,OH^- + C_6H_5.CH_2OH$
$= 4\,MnO_4^{--} + 4\,H_2O + C_6H_5COO^-$
10. $4\,MnO_4^- + 5\,OH^- + C_2H_5OH = 4\,MnO_4^{--} + CH_3COO^- + 4\,H_2O$
11. $4\,MnO_4^- + 5\,OH^- + CH_3.CH_2CH_2OH$
$= 4\,MnO_4^{--} + CH_3.CH_2.COO^- + 4\,H_2O$
12. $4\,MnO_4^- + 5\,OH^- + CH_3.CH_2.CH_2.CH_2OH$
$= 4\,MnO_4^{--} + CH_3.CH_2.CH_2.COO^- + 4\,H_2O.$

Experimental

A known weight of the substance was added to a known excess of standard potassium permanganate solution to which 10 c.c. to 30 c.c. of 30% sodium hydroxide solution had already been added. The mixture was allowed to stand for ten minutes at 45°C. About 10 c.c. to 30 c.c. of 30% barium chloride solution was then added to the mixture and the excess of potassium permanganate solution titrated back potentiometrically against standard sodium formate solution. In these titrations the mixture was kept stirred by a mechanical stirrer.

The oxidation-reduction electrode which consisted of a bright platinum foil immersed in a solution to be titrated, was coupled with a saturated calomel electrode through an agar-agar potassium chloride bridge. The cell was placed in a water bath, the temperature of which was maintained at 45°C. E.M.F. of the cell was read on a potentiometer.

A series of potentiometric titrations were performed with different amounts of each substance. The titrations, one for each substance, are recorded in the following tables:—

TABLE I.—*Titration of 0·1058 gm. of acetaldehyde in presence of 15 c.c. 30% sodium hydroxide, 20 c.c. 30% barium chloride and 40 c.c. 1·0101 N potassium permanganate against 0·1 M sodium formate.*

Discussion

In these titrations with the addition of standard sodium formate, the E.M.F. decreased steadily till the equivalence point. At the equivalence point there was a sharp break in the E.M.F. in each case. For the addition of 0·05 c.c. of the titrant, the inflection potential was of the order of 106, 157, 114, 195, 157, 86, 167, 106, 102, 172, 134 and 156 m. volts for Acetaldehyde, Formaldehyde, Benzaldehyde, Mandelic acid, Cinnamic acid, Tartaric acid, Malic acid, Isoamyl alcohol, Benzyl alcohol, Ethyl alcohol, *n*-Propyl alcohol and *n*-Butyl alcohol respectively.

From the volume of sodium formate used, corresponding to the equivalence point in each titration, the amount of each substance was calculated. The results are given in the following tables:—

Table I.—*Acetaldehyde.*

CATIONOTROPIC REACTIONS WITH ETHYLENIC CARBONYL COMPOUNDS

I. Convenient synthesis of some methoxy Naphthalene Derivatives

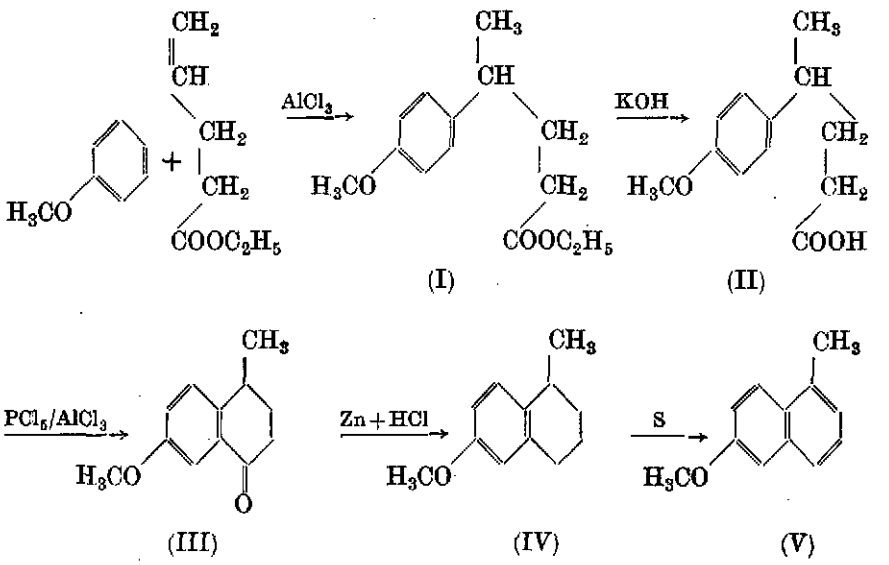
By O. P. Vig, N. K. Maheshwary *and* S. M. Mukherji

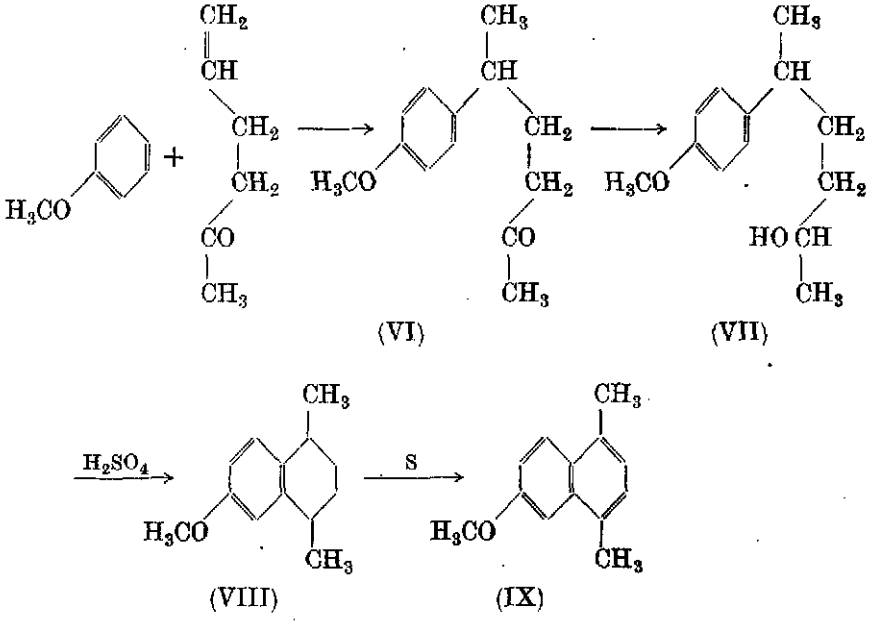
The method developed by Mukherji and co-workers (1, 4, 5, 9–12, 14) was extended to a study of the behaviour of anisol when subjected to aluminium chloride-catalysed reaction at 0–5° with ethyl allylacetate and allylacetone. Friedel-Crafts' alkylation of anisol is rather well known (13) and the para-oriented products are the major components, although in the case of condensation of anisol with cyclo-hexene (2), the ortho-isomer was reported to be greater in proportion. However, when anisol was subjected to aluminium chloride-catalysed reaction at 0–5° with ethyl allylacetate, 4-(*p*-methoxyphenyl)-valerate (I) was obtained. This ester (I) on hydrolysis gave a quantitative yield of the corresponding acid (II). That the product (I) was para-orientated was proved by alkaline potassium permanganate oxidation of the acid (II) to *p*-anisic acid. Furthermore, the acid (II) was cyclized by Johnson's inverse cyclization process (8) to furnish the ketone (*III*) which was smoothly reduced by Clemmensen method (Martin's modification) to the tetralin derivative (IV) followed by dehydrogenation with sulphur to give 1-methyl-6-methoxy-naphthalene (V).



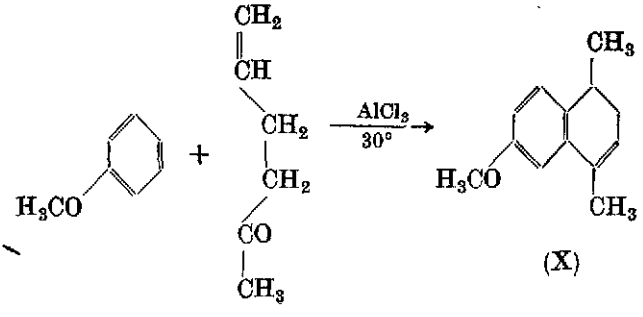
As the yield in the Friedel-Crafts' condensation step was not satisfactory, attempts were made to alkylate anisol under more vigorous temperature

conditions with a view to improving the yield, but extensive demethylation was observed (15).

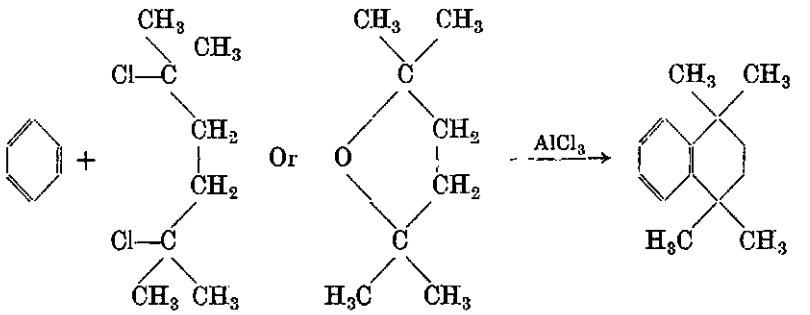
Similarly, anisol was condensed with allylacetone under the comparable conditions when 5-(*p*-methoxyphenyl)-hexan-2-one (VI) was obtained. The orientation in this case was established by sodium hypoiodite oxidation of the ketonic product (VI) to give the same acid (II) as identified through the mixture melting point of their S-benzyl-iso-thiuronium salts. However, the ketone (VI) was reduced with sodium and moist ether to the corresponding carbinol (VII) which was cyclized to the tetralin derivative (VIII) by means of concentrated sulphuric acid. The tetralin derivative was then dehydrogenated to afford a good yield of 1 : 4-dimethyl-6-methoxy-naphthalene (IX).



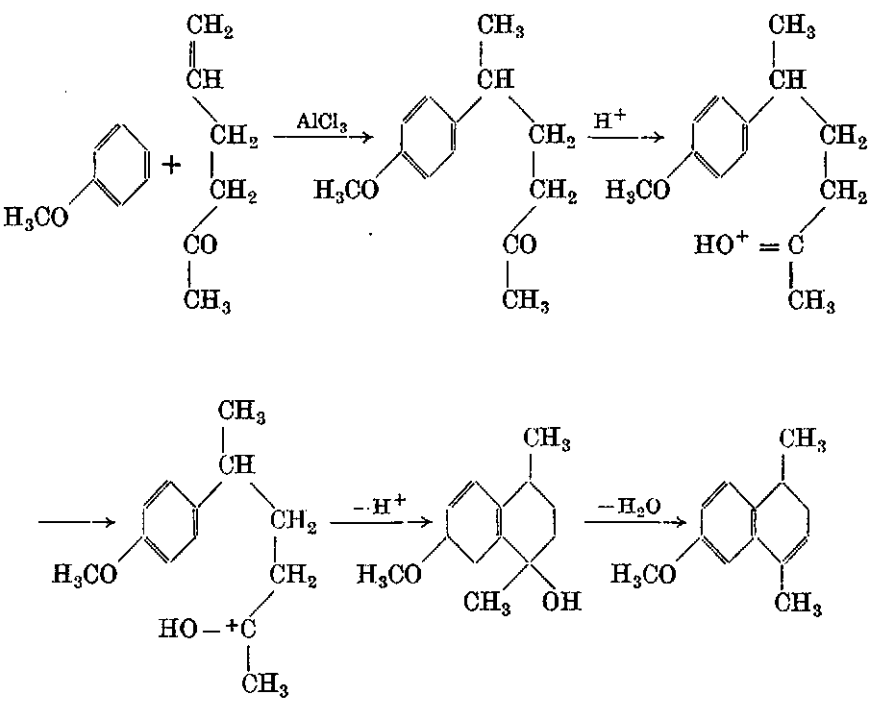
In one of our experiments with anisol and allylacetone, the temperature of the reaction mixture was not controlled so that the temperature rose as high as 30°. It was found that the product from this lot failed to give the semicarbazone. Examination of this product revealed that the initial Friedel-Crafts' reaction at the double bond of allylacetone was accompanied in situ by cyclodehydration to give the dihydro derivative (X).



This was confirmed by dehydrogenation of the product (X) by sulphur to give 1 : 4-dimethyl-6-methoxy-naphthalene. The optimum condition found suitable for the one step synthesis of (X) is described in the experimental section. Although it appears to be very similar with the process of 'cyclialkylation' (3) as under:



our observation may well be explained on the basis of initial Friedel-Crafts' addition of the *p*-methoxyphenyl to the double bond followed by cyclodehydration (6) according to the following scheme:



This observation seems to offer possibility for the development of a still simpler method for the synthesis of naphthalene derivatives in two steps. This possibility encouraged us to extend this method to benzene, toluene, *m*-xylene and naphthalene, which would form the basis of future communications.

Experimental

Melting points and boiling points are uncorrected.
Micro-analyses by Drs. Weiler and Strauss, Oxford.

Ethyl-4-(p-methoxyphenyl)-valerate (I):

Freshly distilled anisol (75 c.c.) and anhydrous aluminium chloride (10 g.) out of a total of 30 g. were taken in a three necked flask (500 c.c.) fitted with a (i) mercury sealed mechanical stirrer, (ii) dropping funnel, and (iii) guard tube and a thermometer. The flask was placed in an ice-bath and the stirrer was started. When the temperature of the resulting mixture came down to 5°, the dropwise addition of ethyl allylacetate was commenced. When half (7 g.) of the total amount was added, its further addition was stopped. About 2-3 g. of anhydrous aluminium chloride was added, followed by the dropwise addition of the remaining ethyl allylacetate (8 g.). The remaining aluminium chloride was then added in small instalments, maintaining the temperature between 5–10° throughout the addition. The addition was complete in an hour and the stirring was continued for another two hours. The reaction mixture was then decomposed by pouring it into iced hydrochloric acid and extracted four times with ether. The ethereal extract was washed once with water, twice with 5% sodium bicarbonate solution and again with water till neutral to litmus. After drying over anhydrous sodium sulphate and removing ether, the liquid was distilled under reduced pressure to give 18 g. (65·2%) of ethyl-4-(*p*-methoxyphenyl)-valerate, b.p. 152–154°/10 mm.

4-(p-methoxyphenyl)-valeric acid (II):

Hydrolysis of the ester (I; 13 g.) was effected by refluxing it with alcoholic potassium hydroxide (potassium hydroxide 7·5 g.; distilled water 5 c.c.; rectified spirit 165 c.c.) for fourteen hours on the water-bath. The alcohol was partly removed and the remaining liquid diluted sufficiently with distilled water. It was extracted twice with ether to remove any unchanged ester (I) and then acidified with dilute sulphuric acid. The liberated oil was taken up in ether. The ethereal extract was washed twice with water and dried over anhydrous sodium sulphate. The solvent being removed, the residue was distilled under reduced pressure, when 10 g. (87%) of 4-(*p*-methoxyphenyl)-valeric acid was obtained as a colourless oil, b.p. 171–173°/6 mm.

S-benzyl-iso-thiuronium derivative:

The acid (II; 1 c.c.) was taken in 10 c.c. of distilled water and two drops of phenolphthalein were added, followed by the addition of a few drops of sodium hydroxide solution. The solution was neutralized with hydrochloric acid indicated by the disappearance of the pink colour. It was warmed and mixed with the reagent prepared by dissolving 2 g. of the same in 10 c.c. of distilled water. Immediate separation of the acid derivative was observed. The acid derivative was crystallized from 50% ethyl alcohol, m.p. 125-126°.

Analysis : Calculated for $C_{20}H_{26}O_3N_2S$: N, 7·48; S, 8·55; C, 64·17; H, 6.95
Found: N, 7·70; S, 8·131; C, 63·94; H, 6·75.

4-methyl-7-methoxy-1-tetralone (III):

Phosphorus pentachloride (11 g.; 1·1 mol) was placed in a 100 c.c. distillation flask fitted with a guard tube on its side arm and covered with 25 c.c. thiophene-free dry benzene. The acid (II) (10 g.; 1 mol) dissolved in dry thiophene-free benzene (20 c.c.) was then added. The reaction mixture was shaken when a violent reaction set in. After the vigorous reaction had subsided, benzene and phosphorus oxychloride were removed under reduced pressure at a temperature not exceeding 90°. Anhydrous aluminium chloride (7·5 g.; 1·1 mol) was placed in a 250 c.c. conical flask carrying a calcium chloride guard tube and immediately covered with petroleum ether (80–100°; 40 c.c.) and the mixture cooled in an ice-salt bath at −10°. The acid chloride was taken up in 20 c.c. thiophene-free dry benzene and cooled in an ice-bath. The thoroughly cooled acid chloride solution was added all at once to the aluminium chloride-petroleum ether mixture and swirled. On warming to room temperature (25°), the reaction started with vigorous evolution of hydrochloric acid gas. When the vigour of the reaction had subsided, the mixture was just warmed on the water-bath at 50° and immediately taken out and the reaction allowed to proceed as such; this was repeated for an hour. The mixture was dark brown in colour. A jelly like complex was obtained which was decomposed by crushed ice and hydrochloric acid. The cyclized compound was extracted with benzene, the extract washed thrice with 5% sodium carbonate solution, then with water and dried over anhydrous sodium sulphate. The residual liquid, left after the removal of the solvent, was distilled under reduced pressure, when 4 g. (44%) of the ketone (III) was obtained, b.p. 102–105°/4 mm.

The semicarbazone derivative was prepared in the usual way and crystallized as colourless crystals from ethanol, m.p. 199-200°.

Analysis : Calculated for $C_{13}H_{17}O_2N_3$: N, 17·00
Found: N, 17·50

The 2 : 4-dinitro phenylhydrazone was prepared in the usual way and was crystallized as orange red needles from ethyl acetate, mp. 214-215°.

Analysis : Calculated for $C_{18}H_{18}O_5N_4$: N, 15·13
Found: N, 15·50.

1-Methyl-6-methoxy-1 : 2 : 3 : 4-tetrahydro-naphthalene (IV):

Preparation of amalgamated zinc: 17 g. of granulated zinc, 2 g. of mercuric chloride, 1 c.c. pure hydrochloric acid and 28 c.c. of distilled water were stirred for about five minutes in a beaker. The aqueous solution was decanted off and the amalgamated zinc washed with distilled water.

Amalgamated zinc (17 g.) was taken in 250 c.c. flask fitted with a reflux condenser. To this was added 3·5 g. of ketone (III), 30 c.c. toluene

20 c.c. water, 1 c.c. glacial acetic acid, 30 c.c. hydrochloric acid and the mixture refluxed in the oil-bath at 130–140° for thirty-six hours. After every six hours, 5 c.c. of pure hydrochloric acid was added. The reaction mixture was cooled and extracted with toluene; the toluene extract washed and dried over anhydrous calcium chloride. The solvent was removed and the residual liquid was distilled under reduced pressure, when 2·5 g. (78%) of (IV) was obtained as a clear oil, b.p. 120–122°/5 mm.

1-Methyl-6-methoxy-naphthalene (V):

The above product (2·5 g.) was heated with 1·1 g. of sulphur in a sulphuric acid bath for ten hours. The dehydrogenated product was then submitted to steam distillation. The distillate was taken up in ether and worked up in the usual way, when 1·6 g. (66·6%) of 1-methyl-6-methoxy-naphthalene was obtained, b.p. 135°/10 mm.

The picrate of (V) was prepared in the usual manner and crystallized as orange red needles from 80% ethyl alcohol, m.p. 144-145° (shrinkage at 136°).

Analysis: Calculated for $C_{12}H_{12}O$, $C_6H_3N_3O_7$: N, 10·47
Found: N, 10·30.

Oxidation of the acid (II) with alkaline permanganate:

The acid (II; 2·5 g.) was oxidized with alkaline potassium permanganate solution (prepared from 15 g. of potassium permanganate, 300 c.c. of distilled water and 2-3 pallets of sodium hydroxide) by refluxing for eight hours. The manganese dioxide precipitate was removed by filtration. The colourless filtrate was reduced to a small bulk by evaporation on the water-bath and then acidified with hydrochloric acid. *p*-Anisic acid was obtained as crystalline precipitate. It was recrystallized as colourless crystals from water, m.p. 182-183° decom. (lit. 7) m.p. 184° decomp.

5-(p-Methoxyphenyl)-hexan-2-one (VI):

A mixture of freshly distilled anisol (100 c.c.) and anhydrous aluminium chloride (12 g. out of total required quantity of 36 g.) was placed in a three necked flask (500 c.c.) carrying (i) a mercury sealed stirrer, (ii) a thermometer and a calcium chloride guard tube, and (iii) a dropping funnel. The mixture was stirred vigorously and cooled in ice-bath. As soon as the temperature of the reaction mixture came down to 2°, about 10 g. of allylacetone out of the total of 20 g. were added dropwise to the contents of the flask. A small amount of anhydrous aluminium chloride was then added, followed by the dropwise addition of the remaining 10 g. of allylacetone maintaining the temperature between 0–5°. The rest of aluminium chloride was added in portions under controlled conditions of temperature. The addition was completed in an hour and the stirring was continued for another two hours in the ice-bath. The reaction mixture was kept overnight in an ice chamber and then decomposed in the usual way (vide *supra*), when 13 g. (31%) of 5-(*p*-methoxyphenyl)-hexan-2-one was obtained, b.p. 136–140°/7 mm.

The semicarbazone derivative was prepared in the usual way and crystallized from dilute ethanol, m.p. 151–152°.

Analysis: Calculated for $C_{14}H_{21}N_3O_2$: C, 63·87; H, 7·98; N, 15·96.
Found: C, 63·32; H, 8·30; N, 15·72.

5-(p-Methoxyphenyl)-hexan-2-ol (VII):

The ketone (VI; 6 g.), 100 c.c. of ether and 5 c.c. of water were taken in a flask fitted with a condenser. Metallic sodium (5·5 g.; 8 atoms) was cut into pieces and slowly added to the ketone. Whenever the reaction with sodium subsided, 1-2 c.c. of water was added to facilitate the reaction. After the addition of the required amount of sodium, the product was taken up in ether, washed with water and dried over anhydrous sodium sulphate. After removing the ether, the viscous liquid was distilled under reduced pressure, when 4 g. (66·6%) of 5-(*p*-methoxyphenyl)-hexan-2-ol was obtained, b.p. 135-136°/4 mm.

1: 4-Dimethyl-6-methoxy-tetralin (VIII):

The above alcohol (4 g.) was placed in a conical flask (100 c.c.) fitted with a guard tube and cooled in ice. Sulphuric acid (8 g.; 1·84 d) was added gradually with constant shaking within fifteen minutes and shaking was continued in the bath for another thirty minutes. The contents were then allowed to attain the room temperature. The resulting mixture was decomposed by pouring into iced water and extracted with ether. The ethereal extract was washed with water, 5% sodium carbonate solution, again with water and dried over anhydrous sodium sulphate. After removing the solvent, the residue was distilled under reduced pressure, when 2·5 g. (69·5%) of the tetralin derivative (VIII) was obtained, b.p. 195–200°/12 mm.

1: 4-Dimethyl-6-methoxy-naphthalene (IX):

The product (VIII; 2 g.) was heated with 0·900 g. of sulphur in a sulphuric acid bath for ten hours at 180–190°. The dehydrogenated product was obtained by steam distillation. The yellow coloured oily drops in the distillate were taken up in ether and worked in the usual way, when 1: 4-dimethyl-6-methoxy-naphthalene, b.p. 156–158°/12 mm., was obtained in 52·6% yield.

The picrate of (IX) was prepared in the usual manner and crystallized from ethanol, m.p. 107-108°.

Analysis: Calculated for $C_{13}H_{14}O$, $C_6H_3N_3O_7$: C, 54·94; H, 4·09; N, 10·12
Found: C, 54·36; H, 4·22; N, 9·7.

Oxidation of 5-(p-methoxyphenyl)-hexan-2-one with sodium hypoiodite:

The ketone (VI; 3 g.) was dissolved in 60 c.c. of dioxan and 80 c.c. of 10% sodium hydroxide solution. The mixture was well stirred. Some iodine solution (prepared in the ratio of KI : I_2: H_2O: : 2: 1: 4) was added when a yellow colour developed. The addition of iodine solution was

continued till the dark red colour of iodine persisted in the cold as well as on warming the mixture on the water-bath (60°) for 2-3 minutes (about 120 c.c. of iodine solution was required). The excess of iodine was removed by adding a few drops of dilute sodium hydroxide solution. The reaction mixture was allowed to stand when iodoform, formed during the oxidation, separated at the bottom. The aqueous layer was decanted off and it was extracted with ether to remove any unchanged ketone (VI). The ethereal extract was rejected. The aqueous layer was acidified with dilute sulphuric acid and the liberated iodine was discharged with sodium bisulphite. The oily product was taken up in ether, washed and dried over anhydrous sodium sulphate. The liquid, left after the removal of ether, was distilled in vacuum, when 4-(*p*-methoxyphenyl)-valeric acid (II) was obtained, b.p. 178°/7 mm.; yield: 1·65 g. (55%).

The S-benzyl-iso-thiuronium derivative was prepared in the usual way and crystallized from dilute ethyl alcohol, m.p. 124–125°, undepressed when mixed with the sample previously prepared.

Friedel-Crafts' Reaction at Higher Temperature:

Between anisol and allylacetone:

1: 4-Dimethyl-6-methoxy-1 : 2-dihydro-naphthalene (X):

Freshly distilled anisol (50 c.c.) was placed in a three necked flask having (i) a mercury sealed stirrer (ii) a dropping funnel, (iii) a thermometer and a calcium chloride guard tube. 6 g. of anhydrous aluminium chloride was added to anisol and the contents of the flask were cooled in an ice-bath. The stirrer was started and, as soon as the reaction mixture attained the desired temperature (5°), dropwise addition of allylacetone was commenced. When about 5 g. of allylacetone out of the total quantity of 10 g. was added, its further addition was stopped. About 3 g. of aluminium chloride was added, followed by the dropwise addition of the remaining 5 g. of allylacetone. Then the remaining aluminium chloride was added in five equal instalments, maintaining the temperature between 5–10° (forty-five minutes). The ice-bath was removed and the stirring was continued for another one and a half hours at room temperature (25°). The reaction mixture was then heated on the water-bath at 50° for thirty minutes without stirring and then kept overnight at room temperature. It was then decomposed and worked up in the usual way, when the product (X) was obtained in 52·3% yield, b.p. 194–198°/12 mm.

1: 4-Dimethyl-6-methoxy-naphthalene:

The product (X; 5 g.) was dehydrogenated with sulphur (1·04 g.) and the dehydrogenated product was worked up in the usual manner already described, when 2·5 g. (51·1%) of 1: 4-dimethyl-6-methoxy-naphthalene, b.p. 156–160°/12 mm., was obtained.

The picrate was prepared in the usual manner and crystallized from 80% ethanol, m.p. 107°, undepressed when mixed with the previous sample of the product (IX).

Summary

The aluminium chloride-catalysed reactions between anisol and ethyl allylacetate, and allylacetone have been studied leading to convenient syntheses of some naphthalene derivatives such as 1-methyl- and 1, 4-dimethyl-6-methoxy-naphthalene. Preliminary observations on one-step Friedel-Crafts' condensation accompanied by cyclodehydration giving rise to dihydronaphthalene derivatives have also been recorded.

STUDIES ON THE PROTOZOA OF INDIAN FISHES

I. The Morphology and the Systematic Position of the Ciliates inhabiting the Intestine of Fish *Mystus cavasius* (Hamilton).

By Manohar Singh, M.Sc. (Hons.), *Lecturer in Zoology, Government College, Rupar, Distt. Ambala, Panjab (I).*

Preface

Investigation on the Protozoa of Indian Fishes was carried out by the author at the suggestion and under the supervision of the undersigned. The author submitted a thesis in 1951 on the 'Studies of the Protozoa of Indian Fishes' for the award of the M.Sc. degree (Honours School) of the Panjab University, which was assessed by Dr. H. N. Ray, Officer-in-charge, Section of Parasitology, Indian Veterinary Research Institute, Mukteswar. Dr. Ray also conducted the viva voce, and subsequently helped the author in the preparation of the manuscript for publication.

Vishwa Nath,
University Professor of Zoology
and
Head of the Department,
Panjab University College,
Hoshiarpur.

Dated 24-4-1953.

1. Introduction

Work on the Ciliates from the gut of fish is very scanty, though quite a lot of work has been done on Myxosporidia from this host. Schouten (1940) described *Nyctotherus mackinoni* from the faeces of a fish—*Pimelodus clarias*; while some have worked on the ectoparasitic *Trichodina* of fishes. With a view to make a survey of the protozoal fauna of the food fishes of the State of the Panjab, a start was made by examining the intestinal contents of the available local fishes at Ludhiana. During the course of these studies two new Holotrichous Ciliates were encountered in the gut of *Mystus cavasius*; and the object of this paper is to describe in detail the morphology of these new Ciliates.

It will appear from the description, given below, that a new family *Nathelliidae* [1], with the new genus *Nathella*, had to be created to embrace the two new species, viz., *N. rayii* [2], and *N. Kumarii* [3].

2. Material and Methods

The greatest difficulty was encountered in procuring the material for study. I had been examining the intestine of the common mud-fish, *Ophiocephalus punctatus*, at Hoshiarpur, for about six months (from November, 1949 to March, 1950), but none was found to be infected. In the month of April *O. punctatus*, from Ludhiana ponds, were also examined with negative results. From a village Jassian (Ludhiana) pond I got a specimen of *Mystus cavasius* (Hamilton), vernacular, *Tengra* (Plate 1, Fig. 1), which was found to be infected with Ciliates. Being encouraged by this finding, attention was then solely directed towards this fish, for procuring the required material for study.

From time to time this particular fish was collected and the Ciliates found in its intestine were examined both in their living condition as well as in fixed and stained preparations. In order to study the morphology in detail, the infected portions of the intestine were fixed in Bouin's fluid for 12 hours, Flemming's without acetic acid or Champy's fluid for 24 hours in each, and then cut into thin sections (3–5 μ thick).

It was observed that the infected fish used to die within a period of a few hours when brought out from its normal environments. Various methods were adopted to carry the living fish from Ludhiana to Hoshiarpur, but only the infected ones used to die on the way, while the uninfected ones could survive the journey and remain alive for months together. This is highly suggestive of this Ciliate playing a pathogenic rôle, although confirmatory experimental proof is still lacking. Most of the Ciliates were found to be moving freely in the lumen of the intestine, while a few were seen in close contact with the intestinal epithelium. The presence of trichocysts, however, indicates that this Ciliate is non-parasitic in habit. It will, therefore, be of great interest to study the relationship of this Ciliate to its host.

Infected fish were found to be very rare. As the Ciliates could be seen with the naked eye, instead of carrying them to the laboratory, I could dissect the fish at the source (*Budha Nala*) and keep the infected intestine in normal saline. The stomach proved to be uninfected. Behind the stomach, a little portion of the intestine, i.e., about one-fourth of the entire intestine, was found to be rarely infected. After this region the infection

---

[1] The family is named after Prof. Vishwa Nath, under whose supervision the entire work was planned and carried out in the Zoology Department, Panjab University, at Hoshiarpur.

[2] This new species is named after Dr. H. N. Ray, the Protozoologist, Indian Veterinary Research Institute, Mukteswar, Kumaon (U.P.).

[3] This new species is named after Dewan Anand Kumar, Vice-Chancellor of the Panjab University.

increased proportionately towards the posterior region. The uninfected intestine was found to be very narrow and contained very little food material, but the intestine of the infected ones was invariably very highly distended and filled with food material, consisting of Gastropods, insects, Crustaceans and other aquatic organisms. In a collection, females outnumbered the males and it was observed that the infection was mostly confined to them. From the observations so far made it cannot, however, be definitely asserted that the Ciliates have any particular preference for the sex of the host.

It was very interesting to observe that other carnivorous fishes, living side by side with *Mystus cavasius*—a purely carnivorous fish—were found to be entirely free from this Ciliate, although trematodes, nematodes and tape-worms were found to infect them. The Jassian pond, which is about three miles from Budha Nala, contained many species of carnivorous fishes, but none of them except *M. cavasius* was infected with these Ciliates.

Why these Ciliates prefer the gut of *M. cavasius* and not the other carnivorous fishes, living in the same environment, is a problem which requires elucidation.

Other carnivorous fishes that were found negative for Ciliates are:—

1. *Wallagonia attu* (Block & Schneider) .. Mullee.
2. *Mastacembelus armatus* (Lacepede) .. Bam or Groj or Samp machli.
3. *Ophiocephalus marulius* (Hamilton) .. Saul.
4. *Nandus nandus* (Hamilton) .. Khotah or Gadha.
5. *Colisa fasciata* (Block & Schneider) .. Chidu or Kangee.
6. *Colisa lalius* (Hamilton) .. .. Chhoti Kangee.
7. *Callichrous bimaculatus* (Block) .. Pallu or Pafta.

Their food habit was apparently the same as that of *M. cavasius*. Even the other species of *Mystus* (*M. vittatus* (Block), *Kengar*) and (*M. aor* (Hamilton) *Shinghari*), were found to be uninfected. More than 20 specimens of each of these fishes were examined from different localities but none of them showed any infection.

Fixatives Used:—

Both histological and cytological fixatives were used in these studies.

1. *Osmic acid Preparation.*—The Ciliates were uniformly spread on a cover glass that was previously besmeared with a thin layer of Mayer's egg-albumen. This cover glass was then placed on the mouth of the bottle which contained 2 per cent osmic acid. The osmic vapour was allowed to act for a varying period (from 5 seconds to 10 minutes) followed by washing in 50 per cent alcohol and dehydration (one minute in each dehydrating alcohol) and then mounted in Canada Balsam. Films fixed with osmic vapours were also stained with Giemsa's stain or Heidenhain's iron haematoxylin, or crystal violet. For the latter, the fixed material was kept in 0·005 per cent crystal violet for 18–24 hours, at a temperature of 22°–24°C. Differentiation was carried out with clove oil, under the microscope, and subsequently mounted in Canada balsam after washing in xylol.

2. *Bouin's Fluid.*—The material was fixed in Bouin's fluid from 10 minutes to 2 hours. This fixative produces shrinkage. Its action on the lipoidal material was also observed which was dissolved by the fluid. Portions of the infected intestine were also fixed in Bouin's fluid.

Smear preparations as well as the sections were stained with Delafield's haematoxylin, Ehrlich's haematoxylin, Haedenhain's iron-haematoxylin and Mallory's triple stain.

3. *Kolatchev's Method.*—The material was fixed in Champy's fluid for 24 hours and washed in running tap-water for about the same period. Hot fixative was found to be effective in sticking the animalcules to the cover-slip. The material was then placed in 2 per cent osmic acid at a temperature of 30°–37°C., in the dark, for 3–6 days. Washing was again done for some hours, prior to dehydration, and subsequent mounting.

4. *Da Fano's cobalt nitrate modification.*—The material was fixed for 2 hours in the fixative containing 100 c.c. of a 1 per cent cobalt nitrate solution in distilled water and 15 c.c. of formalin. After fixation, it was washed quickly in distilled water and placed in one per cent silver nitrate solution in the dark for 12–48 hours. To remove the excess of silver, the material was given a quick wash in distilled water. For the reduction of silver nitrate, Cajal's hydroquinone formalin (reducing)[1] mixture was used for 12–48 hours.

5. *Flemming's fluid without acetic acid (F.W.A.).*—Fixation was done in F.W.A. for 24 hours. Time for washing the smears was reduced to 2–4 hours, but for sections the material was washed for 24 hours.

6. *Sudan IV Technique.*—The material was fixed in 4 per cent formalin for 24 hours; washed in distilled water for 5 minutes. The specimens were then transferred, fairly quickly, from 30 per cent, 50 per cent, 70 per cent alcohols to Sudan IV solution for 7–10 minutes. This solution was freshly made in 70 per cent alcohol to saturation. After keeping the material in the stain for 7–10 minutes, the smears were passed through 50 per cent, 30 per cent alcohols to distilled water and mounted in glycerine, the cover-glass being sealed with paraffin wax or gold-size.

7. *Schaudinn's sublimate alcohol.*—Fixation was carried out from 10 minutes to 1 hour. This is the best fixative for the Ciliates. Almost every stain was tried on the organisms after fixation in this fluid.

8. *Zenker's acetic fluid.*—Fixation was carried out from 4–6 hours and then the material was washed in tap-water for 24 hours.

9. *Carnoy's fixative.*—Films were fixed from 10–30 minutes. Washing was done in rectified (several changes) from 6–12 hours.

10. *Concentrated solution of hot corrosive sublimate.*—A drop containing the organisms was spread over a cover-slip and before the preparation was completely dried, the cover-slip was inverted over hot corrosive sublimate solution. The animalcules could, by this way, be made to stick to the

---

[1] Hydroquinone .. .. 1 gram.
Distilled water .. .. 85 c.c.
Formaldehyde (neutralized) 40 per cent .. .. 15 c.c.
Sodium sulphite (anhydrous) .. .. .. 0·15 gram.

cover-glass very firmly. No Mayer's egg-albumen was used for making the smear.

11. *Iodine vapour.*—A few crystals of iodine were put in a test tube. The Ciliates were spread on a slide in a drop of water. The test tube, with iodine crystals, was heated and the brownish green vapour that came out was allowed to pass over the Ciliates on the slide for a few minutes. A drop of water was added and the slide was warmed a little to remove the excess of iodine.

12. *Klein's dry silver method.*—The smear on the cover-slip was dried and then put in 2 per cent silver nitrate solution, in the dark, for 15–30 minutes. It was rinsed in distilled water and exposed to diffuse sunlight, from time to time, watching under the microscope till the ciliary lines were clearly visible. The cover-slip was then dipped in a very weak solution of hyposulphite of soda (one or two crystals in 100 c.c. of distilled water) for a very short period (one or two dips). The smear was finally dried in air and mounted in Canada balsam.

Stains used:—

The following stains were used:—

1. *Borax carmine.*—Half an hour was sufficient for the stain to penetrate. Differentiation was done in acid alcohol.

2. *Delafield's haematoxylin and Ehrlich's haematoxylin.*—These were used to stain the individual Ciliates in smears and in mass. Sections were also stained with these stains. Differentiation was carried out with 1 per cent hydrochloric acid in 70 per cent alcohol. The material was then counterstained with Eosin or Chromotrop 2 R.

3. *Heidenhain's iron haematoxylin.*—The material fixed in Schaudinn's, Bouin's, F.W.A., Zenker's or Carnoy's, was stained with iron haematoxylin. After mordanting with 4 per cent aqueous solution of iron alum for 6 hours, and, washing in distilled water, the specimens in smears or in sections were placed overnight in 0·5 per cent solution of haematoxylin in distilled water. Differentiation was done with 1 per cent iron alum. Rapid method of staining was also tried in the case of sections. Counterstaining was done with water soluble Eosin or in saturated solution of Chromotrop 2 R in absolute alcohol.

4. *Dobell's iron haematein.*—After fixation in Bouin's or Schaudinn's the material was taken to 70 per cent alcohol and then transferred to 1 per cent solution of iron alum in 70 per cent alcohol for ten minutes (the solution was made by dissolving 1 gram of iron alum in 23 c.c. of warm distilled water and adding 77 c.c. of 90 per cent alcohol). After mordanting, the material was rinsed in 70 per cent alcohol. Preparations were subsequently stained in 1 per cent solution of haematein in 70 per cent alcohol for 2–5 minutes. After rinsing the material in 70 per cent alcohol, differentiation was carried out in the original iron alum solution.

5. *Haemalum and picro-carmine.*—Haemalum solution was diluted with distilled water and the specimens, after fixation in Schaudinn's were kept in it for about five minutes and then taken to picro-carmine solution for 10–15 minutes.

6. *Mallory's triple stain.*—The smears, as well as sections, were stained, after fixation in Bouin's or Schaudinn's fluid in 0·5 per cent aqueous solution of acid Fuchsin in distilled water for 5–10 minutes and then transferred to the second solution for 4–6 minutes. Differentiation was carried out in tap-water.

7. *Bresslau's method of staining with Opal blue.*—To a drop of water containing a large number of organisms a drop of colloidal aniline blue stain (soluble in absolute alcohol) was mixed. The film was dried rapidly by swinging in the air and then mounted in Canada balsam.

8. *Giemsa's stain.*—The specimens were stained for one hour in stock solution. Red and Blue stains were controlled by 0·02 per cent NaOH and 0·1 per cent acetic acid solution respectively.

In order to study the morphology in details, the infected portions of the intestine were fixed in Bouin's fluid and F.W.A. and then 3 μ to 5 μ thick sections were cut.

Photomicrographs were taken with a special Spencer's vertical camera, the source of illumination being an incandescent lamp specially meant for this purpose.

3. (*a*) Observations on Living Ciliates

Infected fish, though rare, gave an abundant supply of Ciliates for making various observations. Observations on the living organisms were made in a 0·75 per cent sodium chloride solution in distilled water, under a cover-slip, usually in a small cavity slide. The shape of the organism remains like that of a broad cigar with the anterior end more tapering than the posterior.

In the freshly cut fish, the Ciliates could be seen with the naked eye as white specks even through the intestinal wall.

The organisms move about very actively among the slimy contents of the gut. The active movement, coupled with the thickness of the body, renders it difficult to observe the Ciliates in their living condition.

When the movements of the Ciliates were slowed with the help of a solution of Ispaghul seeds, the movement of the cilia could be seen very clearly. In free movement the Ciliate used to move forward along the longitudinal axis of the body, as other Ciliates, with body cilia moving in the clockwise direction. The Ciliates never used to turn by the side, but they used to change their position dorsoventrally. When the movements were very brisk, they even used to move in a revolving manner round their own longitudinal axis. When the movements slowed down a bit, they exhibited a longitudinal groove along the surface, called the dorsal surface of the Ciliates. The pellicle, at the anterior end, is thick and resembles a shield which is characteristic of these Ciliates. The opening of the mouth is situated towards the posterior end.

At the anterior end, from where the groove starts, there is seen a type of circling ciliary movement and many minute particles can be seen moving in the clockwise direction in this place. This type of circular movement of the liquid was also seen at the end of the groove where the mouth is located.

In their active movements, they avoid solid particles, which come in their way, by squeezing the extremely pliable body. They can also easily squeeze through narrow spaces by changing the form of the body, becoming more or less elongated, and afterwards assuming the same normal shape. The progress is further facilitated by the rigid, pointed shield-like anterior end, which pushes the debris out of the way.

The movements of the undulating membrane in the groove are very peculiar. At intervals, the undulating membrane moves in a wavy manner antero-posteriorly.

(*b*) Observations on Ciliates in whole mounts and sections

The whole body is clothed with uniform, short and very fine cilia which are arranged in longitudinal rows. The ciliary lines are very close to each other (Plate 1, fig. 2, *Cl.*; Plate 2, fig. 6, *Cl.*; Plate 3, fig. 13, *Bc.*, fig. 17, *Cl.*; Plate 5, fig. 25, *Cl.*).

The peristomial groove starts from the anterior end, i.e., from the centre of the anterior shield-like portion. In *N. rayii* the groove in the beginning turns a little to the left side of the body, but later on it turns to the right and ends in the middle of the posterior region; while in *N. kumarii*, it keeps itself to the left hand side of the body and dips to the right (Plate 2, fig. 6, *Pgdv.*; Plate 3, fig. 15, *Pgdv.*; Plate 4, fig. 21, *Pgdv.*) and turns upwards on the ventral surface, ending almost in the centre of the posterior region (Plate 2, fig. 6, *Pgvs.*; Plate 3, fig. 15, *Pgvs.*; Plate 4, fig. 21, *Pgvs.*). The anterior one-fourth region in *N. rayii* and one-sixth in *N. kumarii* is a little bit dilated than the remaining portion, which is uniform throughout its length (Plate 1, fig. 2, *Pg.*; Plate 2, fig. 6, *Pg.*; Plate 4, fig. 19, *Pg.*; Plate 6, figs. 33, 34). The peristomial groove is about 3-4 μ deep, on the surface of the Ciliates, and disappears in 3-4 μ thick serial sections (Plate 3, fig. 17 (complete peristomial groove); Plate 4, fig. 18, *Pg.d*). The undulating membrane (Plate 2, fig. 8, *Um.*; Plate 3, figs. 14, 17, *Um.*; Plate 5, figs. 23, 25, *Um.*; Plate 6, figs. 35, 36) is seen arising from a closely set row of basal granules (Plate 2, fig. 8, *bgum.*; Plate 3, fig. 14, *bgum.*). On the outside, just besides these closely set row of basal granules, there is a row of peristomial fibres (Plate 3, figs. 13, 14, *Pf.*). On the opposite side of the undulating membrane, along the right border of the groove, there is a row of lamellae directed towards the anterior end (Plate 2, fig. 8, *L.*; Plate 3, figs. 13, 14, 17, *L.*; Plate 5, figs. 23, 24, 25, *L*). The outer ends of the lamellae are joined with one another by means of small septa (Plate 3, figs. 13, 14, *S*). These lamellae are thicker than the body cilia and the cilia present on the left side of the groove. The undulating membrane occupies about half the breadth of the groove. In front of the undulating membrane there is a row of small papillae forming a ridge (Plate 2, fig. 8, *R.*; Plate 3, figs. 13, 14, 17, *R.*; Plate 5, fig. 23, *R.*). Each papilla is like an inverted *U*, the function of which is almost the same as that of an undulating membrane. The arms of the papilla, which form inverted *U*-shaped structure, arise from the basal granules (Plate 2, fig. 10, *bgr.*; Plate 3, fig. 14, *bgr.*). The undulating membrane and the ridge stop short in front of the mouth.

The lamella on the right margin and cilia on the left continue. On the left outer side of the groove, there is a row of very long and fine cilia (longer than the body cilia) (Plate 2, fig. 8, *olc.*; Plate 3, figs. 13, 14, 17, *olc.*; Plate 5, fig. 23, *olc.*) arising from the basal granules situated close to the inwardly directed fine cilia. On the inner left hand side of the groove, there is a row of very fine cilia touching the papillae of the ridge (Plate 2, fig. 8, *ifc.*; Plate 3, figs. 13, 14, 17, *ifc.*; Plate 5, fig. 23, *ifc.*). The basal granules of these cilia are rod-shaped (Plate 2, fig. 10, *rsbg.*; Plate 3, fig. 14, *rsbg.*) and so closely arranged that they form the pseudolamellae. Amongst the longer outer cilia are attached a few crescent-shaped trichocysts provided with an opening (Plate 4, fig. 22, *otr.*), towards the anterior end of the ciliates.

At the posterior end of the groove is the mouth which is protected by a guard cirrus (Plate 5, fig. 24, *Cr.*). The mouth, then, opens into the body (Plate 5, fig. 26, *Mo.*) through the cytostomal groove (Plate 5, fig. 24, *Cg.*).

The anterior portion of the groove has got a 'comma'-shaped cirrus (Plate 4, figs. 19, 20, *Cr.*).

The macronucleus (Plate 1, fig. 2, *Mn.*; Plate 2, fig. 6, *Mn.* See Tables 1, 2, 3, 4) is seen in the living ciliate as a clear granular area usually near the middle of the body, but sometimes it may be placed anteriorly or posteriorly. The outline of the macronucleus is nearly always variable due to the food-vacuoles and lipoid inclusions pressing against it. In fixed and stained specimens, it is seen to be surrounded by a delicate thin membrane, which, in sections, becomes very obvious. Within this thin nuclear membrane, the granular nuclear material (Plate 5, fig. 28, *Gm.*) is closely packed. The macronuclear material is typically contracted away from the membrane in fixed individuals. The chromatin appears to be distributed in the form of numerous small granules. The size of the macronucleus ranged between 49·5μ–82·8μ in length and 19·8μ–41·4μ in breadth as determined by measuring 12 living specimens, the average being 65·7μ by 29·79μ; and 26·4μ–82·5μ in length and 13·2μ–33·0μ in breadth as determined by measuring 54 fixed specimens, the average was 53·07μ by 21·61μ in *N. rayii*. In *N. kumarii*, the size of the macronucleus ranged between 46·2μ–75·9μ in length, and 19·8μ–33·0μ in breadth as determined by measuring 10 living specimens, averaging 60·06μ by 27·29μ; and 36·3μ–82·5μ in length and 9·9μ–28·0μ in breadth as determined by measuring 42 fixed specimens, the average was 50·0μ by 21·19μ. The long axis of the macronucleus in relation to the long axis of the organism may be transverse, oblique or parallel.

The spherical micronucleus, which is very small, lies close to the macronucleus, frequently in a depression on the surface of the latter (Plate 1, fig. 2, *Mn.*; Plate 2, figs. 6, 11, *mn.*). It is heavily stained with Heidenhain's iron haematoxylin, following fixation in some strong fixative. In such preparations the chromatin mass is contracted away from the micronuclear membrane.

Micronucleus, as usual, takes a very active part in division. When it just starts to divide, the internal granular material contracts, and gets collected in the middle and then becomes lengthened (Plate 5, figs. 28, 29, 30). On division two micronuclei are formed which remain connected with each other by a very minute spindle (Plate 5, fig. 31, *Sp.*).

The following Tables I–IV will give an analysis of measurements, etc., of a number of individuals.

There is one contractile vacuole present in the posterior region of the body (Plate 1, fig. 2, *Cv.*; Plate 2, fig. 6, *Cv.*; Plate 4, fig. 21, *Cv.*; Plate 6, figs. 33, 34). The contractile vacuole situated in the posterior part of the body opens to the exterior by a small canal (Plate 1, figs. 4, 5). Sometimes there is one lateral contractile vacuole also. The portion of the body is a little bit pushed outside due to its opening. The size of the contractile vacuole is very small. In living individuals, the contractile vacuole is emptied at intervals of 5–10 minutes. After systole, several small vacuoles appear at the same spot which quickly coalesce to form a new contractile vacuole.

The contractile vacuole has got small auxiliary vacuoles (Plate 1, fig. 3, *aw.*), which open into the central bigger contractile vacuole (Plate 1, fig. 3, *oa.*). These auxiliary vacuoles, after pouring their contents into the main contractile vacuole, reappear again at the same place after sometime (Plate 1, fig. 3, *av*).

The body is clothed with longitudinal rows of short, fine and closely set uniform cilia. The cilia are seen to arise from the inner thinner layer and penetrate through the pellicle, which, in whole mounts, looks to be very thick, but in sections, basal granules are clearly visible, situated quite close to one another (Plate 2, fig. 8, *Bg.*; Plate 3, fig. 16, *Bg.*; Plate 4, figs. 18, 20, *Bg.*; Plate 6, fig. 37). The cilia vary from 1·6μ–4·9μ in length, averaging 4·3μ in *N. rayii*, and 3·3μ–6·6μ in length, averaging 4·75μ in *N. kumarii*. The cilia on the peristomial groove are quite different from the body cilia.

The trichocysts are arranged along the left hand border of the groove in between the longer cilia. Some of the trichocysts are scattered throughout the body (Plate 2, fig. 9, *Tr.*; Plate 3, figs. 18, 22, *Tr.*; Plate 5, fig. 27, *Tr.*), but most of them are found clustered near the anterior end (Plate 4, fig. 22). They are crescent shaped or appear as bent or curved needles with one end drawn out into a filament (Plate 2, fig. 7). In the section of the Ciliates, they are seen in different shapes and positions; some are straight while others are curved. The organism is provided with a power to use these trichocysts, whenever needed and so some of them are thrown out at one time into the surrounding medium. In the sections of the intestine, they were found to be scattered, in the disintegrated intestinal epithelium.

Myonemes are of two types:—(*a*) Longitudinal, (*b*) Circular.

Longitudinal myonemes, are placed slightly on one side of the anterior portion of the groove and run downwards in the cytoplasm. Their direction is more or less oblique (Plate 2, fig. 8, *Lm.*; Plate 4, figs. 19, 20, 22, *Lm.*). Anteriorly, at their origin, they occupy a larger space, but gradually they go on decreasing. Ray (1932) described in *Balantidium sushilii* three or four fibres on the left hand side of the peristome. Chakravarty (1935)

saw them in *B. depressum* (Ghosh) as three or four fibres, arising from the left side of the peristome, but in this ciliate there are numerous fibres running downwards. Posteriorly also there is a bundle of fibres near the groove directed upwards and running in the cytoplasm in the same manner as the anteriorly situated fibres (Plate 4, fig. 21, *Lm*). In *N. kumarii* there are a few additional myonemes provided to keep the groove in its position (Plate 3, figs. 12, 15, *Alm.*; Plate 4, fig. 21, *Alm.*).

Circular myonemes are present throughout the entire inner layer of the body (Plate 2, fig. 8, *Cm.*; Plate 3, fig. 16, *Cm.*; Plate 4, figs. 20, 22, *Cm.*; Plate 6, fig. 37). These myonemes are connected with the body cilia and are responsible for the flexibility of the body. They also help in the active movement of the cilia. These circular myonemes according to the nomenclature of Ten Kate, may be called Morphonemes, for they maintain the body form.

In sections of the infected intestine, the Ciliates could be seen scattered throughout the lumen (Plate 6, fig. 32), but it cannot be said definitely whether they are parasitic or non-parasitic to the host. Presence of trichocysts proves them to be entirely non-parasitic, but mortality amongst the infected fishes only, as mentioned earlier, suggests that they may exert some adverse influence on their host. Further studies are, however, needed to settle this question.

Besides the micronucleus another irregular mass of protoplasm is seen to lie near the macronucleus (Plate 6, figs. 33, 34) which takes a faint nuclear stain. The exact nature of this mass of protoplasm has not been determined yet.

No cysts or conjugants could be encountered through the course of the study.

4. Systematic Position

From their superficial appearance the Ciliates resemble *Nicollella* and *Collinella* Chatton and Perard and *Buxtonella* Jameson. For instance, the peristomial groove in *N. rayii* resembles that of *Nicollella*, while in *N. kumarii*, it resembles that of *Collinella*, but on closer examination of their morphology one finds ample grounds for creating a new family for receiving the Ciliates described in this article. For example the presence of membranellae in both *N. rayii* and *N. kumarii* separates them both from *Nicollella* or *Collinella*. Again in *Nicollella* and *Collinella*, the mouth is situated at the anterior end while in these new Ciliates, it is at the posterior end. The presence of a thick pellicle at the anterior margin and the construction of the groove makes it differ from *Buxtonella*. The species of *Nicollella*, *Collinella* and *Buxtonella* have all been described from mammalian hosts, while the Ciliates described here are from the fish. The morphological features of this new Ciliate also differ in many respects from hitherto known families of Ciliates described under the order Holotricha and suborder Hymenostomata.

Order: HOLOTRICHA

Sub-order: HYMENOSTOMATA

Family: Nathelliidae. Fam. N.

The Ciliates, which are quite new, have recently been discovered from the intestine of fish—*Mystus cavasius*.

The Ciliates belonging to this family are Holotrichous Ciliates with body uniformly covered with short and fine cilia arranged in longitudinal rows. The peristomial groove which is always kept on the dorsal surface, while in movement, runs from the anterior region, where the pellicle is thick and shield-like, to the posterior region where either it ends on the dorsal surface, or turns towards the ventral surface. The mouth, which is provided with a cirrus, is situated at the end of the groove. The groove has got an undulating membrane on the right border with a row of lamellae on the outside, and cilia on the inner left border, with rod-shaped basal granules, arranged very closely, so as to form the pseudolamellae. The other cilia are to the outside, and these are longer than the body cilia. The ridge which lies between the inner fine cilia and the undulating membrane is provided with papillae. The anterior portion of the groove is slightly dilated. The undulating membrane and the ridge continue from the anterior to the posterior region, but stop short in front of the mouth. The macronucleus varies in size and shape. The position of the macronucleus in the body is variable. The micronucleus is spherical and is placed in a depression on the surface of the macronucleus. One or two contractile vacuoles may be seen lying at the posterior end of the body. Trichocysts are present, amongst the longer cilia, on the left border of the groove and are also scattered in the body. They are crescent-shaped with one end drawn out into a filament. Longitudinal and circular myonemes are present.

Genus *Nathella*. N. gen.

Characters of the family. The genus embraces two new species, viz., *N. rayii*, n.sp., and *N. kumarii* n. sp.

DIAGNOSIS

Nathella rayii n.sp.

This is Holotrichous ciliate with broadly elliptical body. Body cilia are uniform, fine and arranged along longitudinal rows. Ciliary lines are very closely set. Body cilia vary from $1{\cdot}6\mu$–$4{\cdot}9\mu$ in length. The groove starts from the anterior region and ends posteriorly on the dorsal surface bearing the mouth with a cirrus. Undulating membrane is present throughout the right margin of the peristomial groove. On the anterior region about one-fourth of the peristomial groove is slightly dilated. The undulating membrane stops short a little above the posterior portion of the groove where it just closes encircling the mouth, while the lamellae on the outside continue to the end of the groove on the right border. Length of the

peristomial groove varies from 197·0μ–264·0μ according to the variation in the size of the body. Contractile vacuole usually on the posterior end opens to the outside by a canal and is provided with auxiliary vacuoles. Macronucleus is granular and varies greatly in shape. The spherical micronucleus is situated in a depression on the surface of the macronucleus. Nuclear dimensions range between 49·5μ–82·8μ in length and 19·8μ–41·4μ in breadth. The average being 65·70μ by 29·79μ. The position of the macronucleus in the body is variable. The long axis of the macronucleus is oblique, transverse or parallel to the long axis of the body. Longitudinal myonemes are present at the anterior and posterior regions of the body. Circular myonemes (morphonemes) are present throughout the inner region of the body.

Dimensions: Size very variable. 198·0μ–330·0μ × 125·4μ–181·4μ, averaging 252·68μ × 151·07μ.

Habitat: Intestine of fish *Mystus cavasius*.

Locality: Ludhiana.

Nathella kumarii n.sp.

This is also a Holotrichous Ciliate usually with an elongated body but shows variety of shape and form. Body cilia are short, fine and uniform, arranged along the closely set longitudinal rows. Cilia vary from 3·3–6·6μ in length. The groove starts from the anterior region and passes over the entire dorsal surface, dips to the ventral surface and curves upwards making the shape of *U*. At the end of the peristomial groove is the mouth with cirrus. Undulating membrane is present throughout the length of the groove. About one-sixth of the anterior portion of the groove is slightly dilated. The groove is longer than the length of the body. Contractile vacuole usually on the posterior end opens to the outside by a canal and is provided with auxiliary vacuoles. Macronucleus is granular and very variable in shape. On its surface lies the spherical micronucleus, more or less, sunk in a depression on the surface. Nuclear dimensions range between 46·2μ–75·9μ in length, 19·8μ–33·0μ in breadth, the average being 60·06μ by 27·29μ. The long axis of the macronucleus is oblique, transverse or parallel to the long axis of the body. The macronucleus is anterior, central or posterior in position in the body. Longitudinal myonemes are present at the anterior and posterior region of the body near the start and at the end of the groove. There are myonemes also between the two arms of the groove, obliquely situated, which help to keep the two arms of the U-shaped curvature in their position and also help to keep them at a certain distance. The posterior region of the groove bears a very minute triangular keel or guard to keep the groove in position (Plate 3, figs. 12, 15, *K*). Circular myonemes (morphonemes) are present lining the inner surface of the body throughout.

Dimensions: Size very variable. 145·2μ–297·0μ × 89·0μ–148·5μ averaging 218·79μ by 126·05μ.

Habitat: Intestine of fish *Mystus cavasius*.

Locality: Ludhiana.

5. Acknowledgement

I am deeply indebted to Dr. Vishwa Nath, Ph.D. (Cantab.), F.N.I., Head of the Panjab University Zoology Department and Principal, University College, Hoshiarpur, who suggested to me this probelm and encouraged me in every way in conducting my researches both at Ludhiana and Hoshiarpur, and offering his valuable criticism in the preparation of the manuscript.

I wish to thank Prof. D. R. Puri, Head of the Zoology Department, Government College, Ludhiana, who very kindly permitted me to carry on my research work in his laboratories.

I am deeply indebted to Dr. H. N. Ray, M.Sc. (Cal.), Ph.D. (London), F.N.I., Officer-in-Charge, Section of Parasitology, Indian Veterinary Research Institute, Mukteswar, Kumaon (U.P.), who very kindly examined my preparations and helped me in the identification of the Ciliates, and took the photomicrographs illustrating this article.

I am also thankful to Dr. S. Datta, D.Sc., M.R.C.V.S., D.T.V.M., F.R.S. (Edin.), F.N.I., Director, Indian Veterinary Research Institute, Mukteswar, Kumaon (U.P.), for kindly permitting me to work in the Protozoology laboratory of his Institute.

I also wish to thank the officers of the Fisheries Department, Ludhiana, who made the collection of the fish possible.

6. Summary

The morphology of the two new Ciliates from the intestine of a carnivorous fish—*Mystus cavasius*—(mostly from Budha Nala and often from Jassian Pond, Ludhiana) are described. The morphological characters are identical with the Ciliates belonging to the sub-order Hymenostomata, but a new family *Nathelliidae* and a new *Genus Nathella*, with two new species *Nathella rayii* n.sp. and *Nathella kumarii* n.sp., have been described in detail.

The peristomial groove starts from the anterior end, and finishes just at the posterior end in *N. rayii*, while in *N. kumarii* it continues throughout the posterior surface, dips to the right, and turns upwards on the ventral region. The end of the groove bears the mouth in both. The groove bears the undulating membrane on the right side with lamellae on the outside. The morphology of the groove is the same in both the species. The only difference is that about one-fourth of the anterior portion of the groove in *N. rayii* and one-sixth of the anterior portion of the groove in *N. kumarii*, is dilated, because the groove in the latter is longer, though the length of the dilated portion of the groove is nearly the same in both. The body cilia is shorter in *N. rayii* than those in *N. kumarii*. The macronucleus in *N. rayii* is longer than that of *N. kumarii*. In shape, latter's macronucleus is more complicated than the former's. The macronucleus in *N. rayii* is larger than that in *N. kumarii*. Both have got contractile vacuoles at their posterior ends. These are provided with auxiliary vacuoles. Both have got longitudinal and circular myonemes, but *N. kumarii* has got another bundle of myonemes, obliquely placed, on the dorsal and ventral surface of the arms of the groove. The groove is also provided with a keel

or guard at the posterior end, where the groove just dips to the ventral surface. This keel or guard keeps the groove in position and is present only in *N. kumarii*.

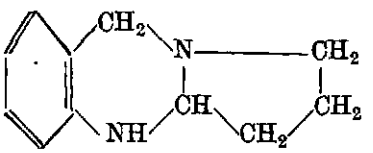
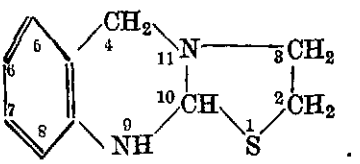
THIOPEGAN DERIVATIVES. PART II.

By M. S. Dhatt *and* K. S. Narang (*Department of Chemistry, Panjab University College, Hoshiarpur, East Panjab, India*).

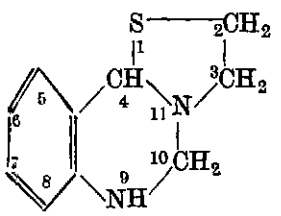
Since Pyrrolidino-Tetrahydro Quinazoline (I) has been named Pegan by Späth,[1] the authors[2] have suggested the name Thiopegan for the structure (II). Since compounds of the Isomeric structures (III) and (IV) are closely related to (II) it is considered desirable to finalize the system of nomenclature in the three compounds. The original nomenclature Thiopegan could be extended to (III) and (IV) by showing the positions in the Quinazoline ring to which the Thiazolidino ring is fused in each of the three isomers. (II), (III) and (IV) would, therefore, be named as 10 : 11 Thiopegan ; 4 : 11 Thiopegan and 9 : 10 Thiopegan, respectively.



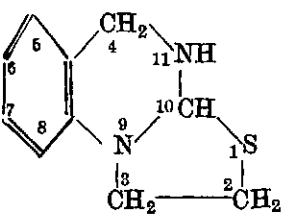
(I)



(II)

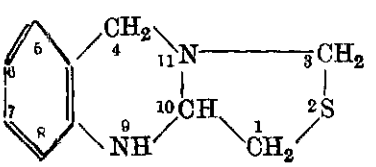


(III)

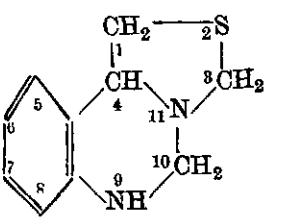


(IV)

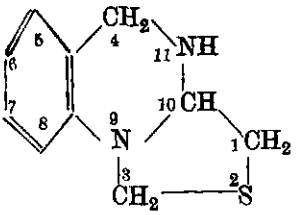
The ring systems (V), (VI) and (VII) with S in position 2 could then be named as 2 Iso-10 : 11 Thiopegan ; 2 Iso-4 : 11 Thiopegan and 2 Iso–9 : 10 Thiopegan, respectively. The ring systems (VIII), (IX) and (X) with S in position 3 could be named as 3 Iso-10 : 11 Thiopegan ; 3 Iso-4 : 11 Thiopegan and 3 Iso–9 : 10 Thiopegan, respectively.



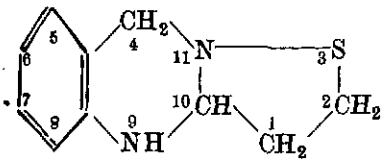
(V)



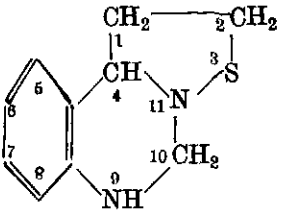
(VI)



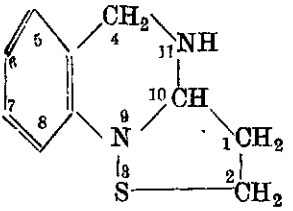
(VII)



(VIII)

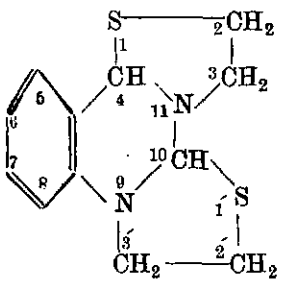


(IX)



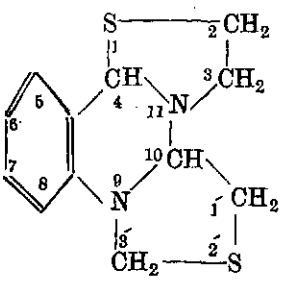
(X)

The ring systems (XI)–(XIX) could be named with reference to one of the Thiopegans or Iso-Thiopegans as shown.



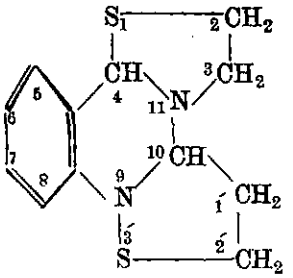
(XI)

1́ Thiazolidino 4 : 11 Thiopegan.



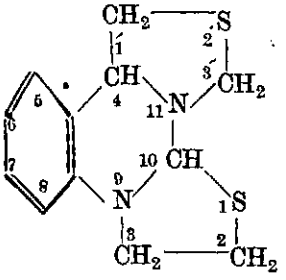
(XII)

2́ Thiazolidino 4 : 11 Thiopegan.



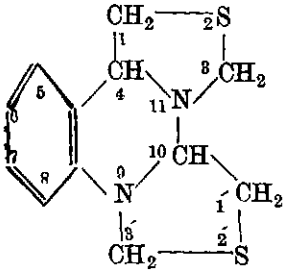
(XIII)

3́ Iso-Thiazolidino 4 : 11 Thiopegan.



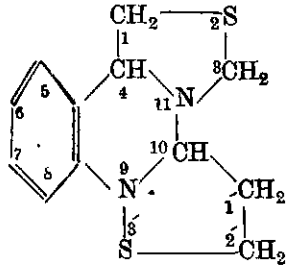
(XIV)

2́ Thiazolidino 9 : 10 Thiopegan.



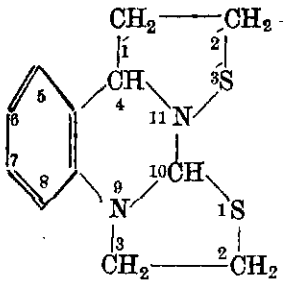
(XV)

2́ Thiazolidino 2 Iso-4 : 11 Thiopegan.



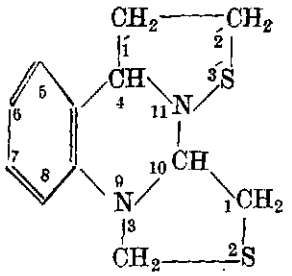
(XVI)

3́ Iso-Thiazolidino 2 Iso-4 : 11 Thiopegan.



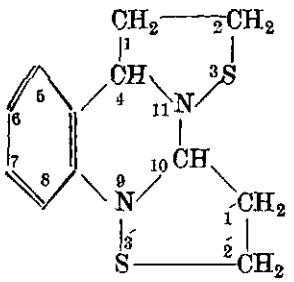
(XVII)

3 Iso-Thiazolidino 9 : 10 Thiopegan.



(XVIII)

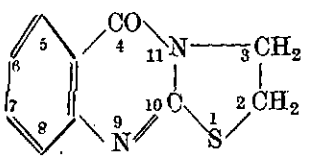
3 Iso-Thiazolidino 2 Iso-9 : 10 Thiopegan.



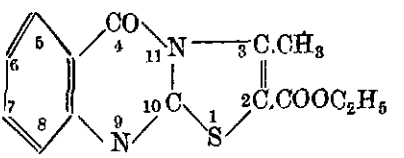
(XIX)

3 Iso-Thiazolidino 3 Iso-4 : 11 Thiopegan.

Apart from the intrinsic interest in the chemistry of these ring systems, their physiological activity is likely to be of some value due to the combined presence of Thiazolidine and Quinazoline rings. The high antimalarial activity shown by 10 : 11 Thiopegen-9, 4-one. (XX) against *P. Gallinaceum* in chicks and prevention of the growth of Mycrobacterium Tuberculosis in a dilution of 1 : 1,000 by 2-carbethoxy-3 methyl 10 : 11 Thiopega-2 : 9 diene-4-one (XXI) have justified the above expectation.

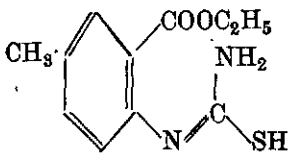


(XX)

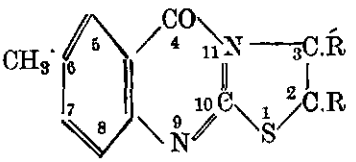


(XXI)

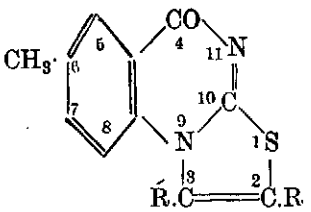
The present communication records the preparation of some Thiopegadiene derivatives (Table I) by the condensation of 2-carbethoxy-4-methyl phenyl thiourea (XXII) with appropriate α-chloro or α-bromo ketones. The products have been tentatively given the general structure (XXIII), but these could also be given the general structure (XXIV). Confirmation of the exact structures by independant synthesis is in progress.



(XXII)



(XXIII)



(XXIV)

R and R̄ are various substituents.

Besides the compounds enlisted below, 2-carbethoxy-4-methyl phenyl thiourea has also been condensed with chloroacetone, α-bromo ethyl acetoacetate and α-chloro-ethyl methyl ketone. The analytical results of the products are awaited

Acknowledgment

The authors are grateful to Dr. S. M. Mukherji, Head and Professor of Chemistry Department, Hoshiarpur, for his kind interest in the work and to Col. Jaswant Singh, Director, Malaria Institute of India, Delhi, for kindly carrying out antimalarial tests.

SPERMATOGENESIS OF *ACHETA DOMESTICUS* LINN. (*GRYLLUS DOMESTICUS*) WITH OBSERVATIONS UNDER THE PHASE CONTRAST MICROSCOPE

By Vishwa Nath *and* Bachittar Singh Bhimber, *Department of Zoology, Panjab University College, Hoshiarpur*

Introduction

Cytologists have long found insecta to be a very fertile field for investigation. Although much work has been done on the cytoplasmic inclusions in the germ cells of Lepidoptera (Gatenby, 1917; Bowen, 1922), Hemiptera (Bowen, 1922-23; Chickering, 1927), Coleoptera (Bowen, 1924; Nath, Bawa, Bhardwaj and Gupta, 1951; Mickey, 1935) and Aptera (Charlton, 1921; Bowen, 1924; Gatenby and Mukerji, 1929; and Nath and Bhatia, 1953), the Orthoptera have received very little attention.

Bowen has done some work on the Orthoptera to which he has made occasional references in his papers on Lepidoptera (1922) and Hemiptera (1922-23). Recently Chang-Chun Wu (1940) has worked out the spermatogenesis of an Orthopteran form, *Diestrammena* sp. with special reference to Golgi bodies and mitochondria. Earlier Payne (1916-17) published his paper on *Gryllotalpa borealis* and *G. vulgaris* and Baumgartner (1902) on 'Spermatid Transformations in Gryllus, etc.'

One of us (B.S.B.) started investigations on the spermatogenesis of *Acheta domesticus* Linn. (*Gryllus domesticus*) in 1952. The material was found to be exceptionally favourable for cytological studies. All preparations have been checked by the senior author, who has also prepared the manuscript for the press. All the figures have been drawn by the junior author.

Studies under the phase contrast microscope were made jointly by us; and they have been remarkably profitable.

Material and Technique

Specimens of *Acheta domesticus* Linn. (*Gryllus domesticus*) were collected from kitchens and storehouses. The male can be distinguished from the female by the absence of an ovipositor.

Specimens were dissected by cutting across the posterior end of the abdomen by a pair of scissors, and the contents were squeezed out in a watch glass containing normal saline solution. Small pieces of the testis not exceeding two mm. in thickness were then transferred to the fixatives.

The material was mostly fixed in Flemming-without-acetic acid for varying periods, and then washed in running tap water or distilled water for the same period. It was then dehydrated and embedded in paraffin wax. Sections were cut five microns thick and were stained in 0·5% iron

haematoxylin after usual mordanting in 4% iron alum. Differentiation was done in 2% iron alum. Some material was also fixed in Champy's Fluid. Bouin's fluid was used for control. Smears for the study of the mature sperms were also prepared. A portion of the testis was pressed between the two slides, which were then placed in F.W.A. diluted with an equal quantity of distilled water for one or two hours. After washing for the same period slides were stained in 0·5% iron haematoxylin. Best results were obtained from the material fixed for 36 hours in F.W.A. and for 12 hours in Champy's fluid.

Observations on the fresh material were also made under the phase contrast microscope.

Observations

Spermatogonium

The earliest spermatogonium (Fig. 62, Pl. IV) of *Acheta domesticus* Linn. (*Gryllus domesticus*) appears as a more or less rounded cell in the living condition under the phase contrast microscope. It contains a comparatively big nucleus, which reveals fine chromatin granules connected by fibres forming a network. One or two nucleoli may also be present in the nucleus. The nucleus of the spermatogonium is so big in some cases that the cytoplasm can be scarcely made out. A few very dark granules are present in the cytoplasm, juxta-nuclear in position.

In sectioned and stained material the spermatogonium shows the same form and structure as in the living condition (Fig. 1, Pl. I), except that the juxta-nuclear mass shows two types of granules, viz., a mass of very faintly-staining, greyish granules, in which are embedded a few bigger and darkly-staining spherical bodies. The former are the mitochondria and the latter the Golgi elements.

During the spermatogonial metaphase (Fig. 2, Pl. I) chromosomes arrange themselves at the equator of the spindle. A centriole is present as a fine granule at each pole of the spindle. The fine, faintly-staining mitochondria cannot be seen at this stage, as they are uniformly distributed in the cell, but a few Golgi granules can be easily detected in the cells as they are bigger in size and stain more deeply with iron haematoxylin.

In polar views of the metaphase plate (Fig. 3, Pl. I) 21 chromosomes can be easily counted; one of these is U-shaped and is the sex chromosome.

Primary spermatocyte

The earliest primary spermatocyte (Fig. 4, Pl. I) shows an oval nucleus, which does not reveal any structure, save for the presence of one or two nucleoli. The mitochondria form one or two deeply-staining, cloudy masses close to the nucleus. Each mass is so dense and compact that it is very difficult to make out the individual granules. In some cases they appear to be composed of threads, which are most probably formed by the alignment of granules. In some cases Golgi spheres are also met with, with only the chromophobic area present, while in others the usual characteristic duplex structure of the Golgi sphere can be easily made out.

At a later stage (Fig. 5, Pl. I) the mitochondria appear as fine granules, which have started spreading around the nucleus. The nucleus is again oval here, and does not show any structure except one or two nucleoli. Golgi bodies are present in the form of crescents, and spheres which show only the chromophobic medulla.

At a still later stage (Fig. 6, Pl. I) the mitochondria become vesicular. They now appear as small vesicles, which are ovoid or spherical. Each vesicle consists of a droplet of some substance, which has no affinity for the stain. This material is enclosed in a delicate envelope of a substance, which takes the haematoxylin stain rather sharply. After some time these vesicles begin to lengthen out and form hollow tubes closed at both the ends. These may be straight or a bit curved (Fig. 7, Pl. I). These tubes further elongate, and their cavities become obliterated. Thus thick mitochondrial threads are formed, which cover the nucleus on all sides. Gradually they are converted into fine threads (Fig. 8, Pl. I).

The primary spermatocytes have been studied in the living condition under the phase contrast (Fig. 63, Pl. IV). As thus studied, the primary spermatocyte is a rounded cell having a spherical nucleus with one or two nucleoli. Mitochondria are present in the form of numerous delicate threads, which form a circum-nuclear ring. Golgi bodies are conspicuous in the cytoplasm in the form of dark granules.

Fig. 64, Pl. IV, has been drawn from a living cell as seen under the phase contrast. The metaphase I chromosomes, the mitochondrial threads forming a mantle round the spindle, a centriole at each pole of the spindle and lastly the Golgi bodies in the form of dark granules can be easily observed. An important point may be noted that the fibres in the spindle area are conspicuous by their absence at this stage. This is fully confirmed by the study of fixed and stained cells (Fig. 9, Pl. I).

In the late telophase stage (Fig. 11, Pl. I) of the first maturation division the Golgi bodies and the mitochondria have been distributed to the two daughter cells. The spindle fibres and mid-body granules are now conspicuous.

Secondary spermatocyte

It may be recalled that the mitochondria, which are granular in the spermatogonia first become vesicular and then thread-like in the primary spermatocytes during the growth period. But in the earliest secondary spermatocyte the mitochondria once more assume the vesicular form (Fig. 12, Pl. I). Soon after, however, the vesicles are converted into threads (Fig. 13, Pl. I), which can be observed very clearly in the living cell also studied under the phase contrast (Fig. 65, Pl. IV).

Metaphase II stages are very rare in our preparations, although one polar view of such a stage has been figured by us (Fig. 15, Pl. I). Telophase II stages, however, are very common in both the fixed preparations as well as in the living cells as studied under the phase contrast (Figs. 14 and 16, Pl. I; and Fig. 67, Pl. IV). In Fig. 16, Pl. I, and in Fig. 67, Pl. IV, the spindle fibres seem to be disappearing; at any rate, they cannot be made out as such from the thick mitochondrial filaments. But since the mid-

body granules are present at this stage (Fig. 67, Pl. IV) it can be safely assumed that the spindle fibres are masked by the mitochondrial threads.

Spermatid and Spermateleosis

The earliest spermatid (Fig. 17, Pl. I) shows a small nucleus, which reveals a comparatively lightly-stained portion, filled with chromatin granules and a small very darkly-staining portion. These portions of the nucleus, i.e. darkly- and lightly-staining, are separated by a narrow clear space. Prominent thread-like mitochondria taking a very dark stain are present. Golgi bodies are present in the form of granules. At a later stage the darkly-staining portion of the nucleus becomes constricted off from the lightly-staining portion (Fig. 18, Pl. I). At a still later stage (Fig. 19, Pl. I) the deeply-staining portion of the nucleus is completely cut off from the lightly-staining portion and starts degenerating. Ultimately it disappears altogether.

After a part of the nucleus has been constricted off, an important change comes over the spermatid nucleus. It now starts staining very feebly and homogeneously (Fig. 20, Pl. I).

After this stage the mitochondria come close together to form the mitochondrial nebenkern, which is characteristic of insect spermatogenesis. The mitochondria pass through various stages of condensation, until the final differentiation of the nebenkern into an outer chromophobic and an inner chromophilic area is established.

In the living condition under the phase contrast, the mitochondria in the earlier stages of condensation form a cloudy mass very close to the nucleus (Fig. 68, Pl. IV). The nucleus is spherical and shows a nucleolus and chromatin granules. Golgi granules are present close to the mitochondrial nebenkern.

In the sectioned and stained preparations, the mitochondrial nebenkern shows a vacuolated structure in its earlier stages (Fig. 21, Pl. II). Contrary to our observations on the living cells, most of the Golgi bodies appear in the form of crescents, although a few Golgi granules may also be present.

The nebenkern now starts rounding up (Fig. 22, Pl. II) till it becomes completely spherical. At the same time it begins to stain homogeneously (Fig. 23, Pl. II). In between the nucleus and the mitochondrial nebenkern a few Golgi crescents can be observed close together. It is most probable that they will fuse together to form the acroblast, but the actual fusion has not been observed by us.

At a later stage, when the acroblast is fully formed, the mitochondrial nebenkern starts differentiating and passes through a series of internal changes. Firstly it becomes spherical and shows vacuoles (Figs. 24 and 26*a*, Pl. II), which are separated by chromophilic plates. At the points where these plates meet, prominent chromophilic thickenings are present in the form of granules. The nebenkern at this stage represents a beautiful artistic pattern.

At a further stage in the condensation of the nebenkern, its cortical portion becomes uniformly thick all round and begins to stain darkly with

iron haematoxylin. The medulla of the nebenkern reveals a vacuolated appearance, the vacuoles being separated by chromophilic plates, which also reach the outer chromophilic cortex (Fig. 26*b*, Pl. II). Prominent granules are present on these plates towards the centre. Generally there is a large granule in the centre of the nebenkern, surrounded by other granules forming a single layer around it.

In the next stage (Fig. 26*c*, Pl. II) the differentiation of the nebenkern into an outer chromophobic and an inner chromophilic zone has started. The cortex becomes thicker than before. Its one half has become chromophobic, while the other half is still chromophilic. Chromophilic plates separating the vacuoles meet as usual the chromophilic part of the cortex, but have been withdrawn from the chromophobic half. Gradually the chromophilic portion of the cortex also becomes chromophobic, and thus a typical insect nebenkern with an outer chromophobic and an inner chromophilic area is formed (Figs. 26*d* and 25, Pl. II). Vacuoles disappear completely from the medullary region. A distinction between the chromophilic and chromophobic portions of the nebenkern could not be observed in the living spermatids (Fig. 69, Pl. IV).

By this time a fully formed acroblast has been formed between the nucleus and the nebenkern (Figs. 24 and 25, Pl. II; Fig. 69, Pl. IV) presumably by the fusion of the Golgi bodies observed in an earlier stage (Fig. 23, Pl. II). Sometimes the acrosomal granule appears in the interior of the acrosomal vesicle (acroblast) almost simultaneously with the first appearance of the acroblast (Fig. 70, Pl. IV). This figure is from a living cell studied under the phase contrast, and it will be noticed that here the acroblast appears in the form of a vesicle and not a crescent. There seems to be hardly any doubt that the crescents are optical sections of spheres. A few Golgi bodies (*G*) do not co-operate in the formation of the acroblast, and they are ultimately sloughed off down the tail.

After the acroblast has been fully formed, an axial filament can be seen arising from the centriole, which is attached to the nucleus (Fig. 25, Pl. II). The axial filament sooner or later comes to lie over the mitochondrial nebenkern and lengthens towards the posterior end (Fig. 27, Pl. II). The spermatid also elongates along its future long axis.

Living spermatids with elongating nebenkerns were frequently observed under the phase contrast microscope. In such a cell the centriole is prominent (Fig. 71, Pl. IV), and in some cases the axial filament can also be seen projecting beyond the free end of the mitochondrial nebenkern (Fig. 72, Pl. IV).

After the mitochondrial nebenkern gets attached to the centriole, it starts elongating along the future long axis of the sperm. It shows the usual chromophobic and chromophilic areas (Fig. 28, Pl. II). Sooner or later the chromophobic area is divided into two halves (Fig. 28*a*, Pl. II). But sometimes the mitochondrial nebenkern begins to elongate before the final distinction into an outer chromophobic and an inner chromophilic area is fully established (Fig. 29, Pl. II).

Shortly after the nebenkern has started elongating a new substance makes its appearance in the outer chromophobic area (Fig. 30, Pl. II). It

appears in the form of very fine granules, which are so disposed that they look like cross lines. This new substance is identical with the 'central substance' of Bowen (1922) or the 'sheath substance' of Nath (1925). The chromophilic area of the nebenkern is now pushed to the posterior end. Golgi remnants (*G*) are seen going back. The nebenkern goes on elongating; its central substance becomes more and more prominent; and its chromophilic area is progressively reduced (Fig. 32, Pl. II) till it ultimately disappears (Fig. 32, Pl. II). With the final disappearance of the chromophilic area the nebenkern divides completely into two right and left halves, which enclose the axial filament between them (Figs. 32 and 33, Pl. II).

The two halves of the mitochondrial nebenkern now spin out into threads. A series of bleb-like swellings appear along each half of the nebenkern, and the intermediate portions become correspondingly thinned out (Fig. 35, Pl. II). A few large swellings first formed (Fig. 34, Pl. II) are sub-divided as the sheaths spin out; and as the sheaths spin out the individual swellings become smaller but much more numerous. Bleb-like swellings sooner or later disappear completely (Fig. 37, Pl. II; and Fig. 38, Pl. III).

During all these stages, i.e. up to the formation of the mitochondrial sheath of the sperm tail, the centriole always remains at the posterior aspect of the nucleus. But after the sheath is formed, it starts moving towards the anterior end of the nucleus. While it moves anteriorly the centriole takes along with it some portion of the mitochondrial nebenkern in the form of blebs (Fig. 36, Pl. II; and Figs. 40, 41, 44 and 46, Pl. III).

Reverting to the subject of acrosome-formation, a prominent granule, the acrosomal granule, is secreted by the acroblast and lies attached to its anterior end (Figs. 40 and 41, Pl. III). This granule is deposited on the nuclear membrane at its posterior aspect. After the acrosomal granule is deposited on the nucleus (Fig. 42, Pl. III) the acroblast starts moving backwards, and is finally sloughed off along with other Golgi bodies (Figs. 45 and 46, Pl. III). Simultaneously, the acrosomal granule itself starts moving forward along the periphery of the nucleus, and deposits itself at its anterior aspect. At the same time the centriole, which formerly had acquired an anterior position, moves backward and reassumes its posterior position. These shiftings of the centriole and the acrosomal granule seem to be partly due to the rotation of the nucleus (Fig. 43, Pl. III).

The acrosomal granule grows in size (Fig. 43, Pl. III), and is then differentiated into the *acrosomal triangle.* This consists of a deeply-staining shelf on which the base of the triangle rests, and a deeply-staining *small granule perched at the apex of the triangle* (Figs. 47, 49 and 52, Pl. III). In Figs. 46 and 48, Pl. III, the shelf of the acrosomal triangle, as seen from above, has been represented. Gradually the shelf of the acrosomal triangle breaks up into fine granules, which later disappear from view, along with the apical granule of the triangle (Figs. 53–58, Pl. III).

The time at which the acrosomal granule is differentiated into the acrosomal triangle varies considerably. This differentiation may take place when the acrosomal granule is at the posterior end of the nucleus, i.e., just after its deposition (Fig. 47, Pl. III); or on its way to the anterior

end (Figs. 44 and 50, Pl. III); or again when the acrosomal granule has reached the anterior end (Fig. 45, Pl. III). Generally this differentiation takes place before the acrosomal granule has reached the anterior aspect of the nucleus.

After the acrosome is formed, the cytoplasm surrounding the nucleus and the axial filament gets attenuated rather suddenly (Figs. 48, 49 and 50, Pl. III). The centriole, which was hitherto only a small granule, increases in size and becomes conical in form (Fig. 49, Pl. III). The nucleus shows a small chromatin granule in its interior. At this stage the nucleus stains feebly, but soon after it starts staining deeply (Figs. 51 and 52, Pl. III).

The nucleus, which was hitherto spherical, now starts elongating. Its posterior region elongates first, and the nucleus thus becomes pear-shaped (Figs. 53-55, Pl. III). The anterior end of the nucleus now also starts elongating and the centriole can no longer be distinguished from the nucleus (Fig. 56, Pl. III). The nucleus further elongates and becomes rod-like with the acrosome at one end and the axial filament at the other (Fig. 57, Pl. III). At a later stage the central portion of the nucleus does not stain as darkly as the peripheral, so that a clear medullary space appears in sections (Fig. 58, Pl. III).

As the nucleus further elongates a deeply-staining spherical body appears at its anterior end, and a similar body appears at a short distance in front of its posterior end. Both these bodies stain deeply with haematoxylin. They are continuous with the chromatin of the nucleus, which is in the form of a spirally arranged coil. This chromatin coil stains deeply at the base of the nucleus, but its staining capacity decreases as we proceed from the base to the apex (Fig. 59, Pl. III).

In a fully ripe sperm the anterior deeply-staining body completely disappears from view, but the posterior one persists. The nucleus is thin and shows chromatin in the form of a spiral thread. This chromatin thread runs for a short distance behind the posterior spherical body. The acrosome in the ripe sperm is small, but the axial filament is very long (Fig. 60, Pl. III).

Fig. 74, Pl. IV, represents a living sperm, which has not yet become fully ripe, as studied under the phase contrast microscope. The chromatin spiral has not yet been fully formed; nor has the anterior nuclear body yet disappeared. It was possible to see many sperms moving under the phase contrast microscope. Movements of the sperm are rhythmical. A wave starts at the anterior end of the sperm and passes backwards. This wave is responsible for the forward movement of the sperm.

Discussion

Perhaps the most important conclusion arrived at in this communication is that the Golgi body is either granular in form or, when it grows, it assumes a vesicular appearance with a chromophilic cortex and a chromophobic medulla. Studies of the fresh material under the phase contrast miscroscope always revealed this spherical form of the Golgi body. The

conclusion, therefore, is inevitable that the crescents met with in sectioned material are the optical sections of the Golgi vesicles.

During the last twenty years or so, Nath has been laying stress on the vesicular nature of the Golgi element (vide Nath, 1944). These views have been confirmed by Baker (1949), who employed the technique of phase contrast microscopy, describing the Golgi element as consisting 'of separate bodies, spheroid in shape'.

Another point, which is worthy of special notice, is that the acrosomal granule, which is the fore-runner of the acrosome, is deposited in the chromophobic interior of the Golgi vesicle or the acroblast (Fig. 70, Pl. IV).

It may also be noted that there is a well-marked process of chondriokinesis inasmuch as each mitochondrial filament is cut across during both the meiotic divisions.

With regard to the spermatid nucleus, it is of special interest to note that it cuts off a small portion, which degenerates in the spermatid cytoplasm (Figs. 17–19, Pl. I). A somewhat similar phenomenon has been described by Bowen (1922, 1922-23, 1924) in the Lepidoptera, Hemiptera and Coleoptera respectively. This phenomenon is obviously related to the condensation of the nuclear contents during spermateleosis.

Lastly mention may be made of two spherical, deeply-staining bodies, one at the anterior end and the other a short distance in front of the posterior end of the nucleus of the maturing sperm (Fig. 59, Pl. III; and Fig. 74, Pl. IV). Soon the anterior body disappears completely, but the posterior one becomes a permanent feature of the ripe sperm (Fig. 60, Pl. III).

Summary

1. The spermatogenesis of *Acheta domesticus* Linn. (*Gryllus domesticus*) has been worked out in this paper.

2. In the spermatogonium Golgi bodies and mitochondria are present in the form of granules. In the primary spermatocyte the mitochondria first appear in the form of one or two cloudy masses. They then become granular and later vesicular, and finally they are converted into threads, which surround the spindle area during the first maturation division.

3. The secondary spermatocyte is like the primary except for its small size. The mitochondria are first in the form of vesicles and later they become thread-like.

4. In the spermatid the mitochondria fuse to form a mitochondrial nebenkern with an outer chromophobic and an inner chromophilic area. The nebenkern elongates, and with the complete disappearance of the chromophilic area, it divides into two halves with the axial filament passing between them. The 'central substance' appears in the chromophobic area.

5. Observations made under the phase contrast microscope have convinced us that the real form of the Golgi body is either granular or vesicular. The acroblast also has been seen in the living cell as a large vesicle, with the acrosomal granule developing within its interior.

6. The nucleus of the ripe sperm is spiral in structure; and a nuclear body at the posterior end of the nucleus is a permanent feature of the ripe sperm.

Explanation of Lettering in the Plates

A.—Acrosome; A_1.—Acroblast; *A.f.*—Axial filament; *A.g.*—Acrosomal granule; *C*.—Centriole; *Ch*.—Chromosome; *C.s.*—Central substance; *G*.—Golgi body; *M*.—Mitochondria; *M.n.*—Mitochondrial nebenkern; *M.b.*—Mid-body; *N*.—Nucleus, N_1.—Nucleolus; *S.f.*—Spindle fibres.

Explanation of Figures

All the figures of the first three plates have been drawn with camera lucida at the table level with 10× eyepiece and oil immersion objective, giving approximately a magnification of 1,700 times, and they are all from fixed preparations. Figures 57, 59 and 60 are from smears. Figures of Plate IV are from the living material studied under the phase contrast microscope.

THE GUINEA-PIG SPERM

By G. P. Sharma, G. C. Chaudhuri *and* V. S. Sattee, *Department of Zoology, Panjab University College, Hoshiarpur*

Introduction

In spite of the fact that mammalian spermatogenesis has been the subject of considerable research for more than half a century, there still remain many controversial points. In most of the available literature *numerous bizarre descriptions of the morphology and functions of certain* cytoplasmic inclusions, especially of the Golgi apparatus, have been given.

The idiosome of the spermatocytes and spermatids aroused a great interest in many workers like Meves (1899) who was indeed much ahead of his times in describing clear granules, each enclosed in a vesicle, embedded in the idiosome. The workers following him, however, ignored this classical work and tried to attribute various shapes to the Golgi elements which are associated with the idiosome. By employing techniques which are far from being satisfactory there has been a good deal of confusion about the form and function of the various cytoplasmic inclusions.

The introduction of a new category of structures, like the 'Post-nuclear granules' of Gatenby and Wigoder (1929) has also stimulated research in the line of tracing the specific action of silver salts on certain cytoplasmic inclusions.

In view of the conflicting and varied descriptions of spermatogenesis in the same animal (*Cavia*) it was felt necessary to reinvestigate the various points in the light of modern work and to arrive at some definite conclusions.

This work was, therefore, started in October, 1942, by one of us (G. C. C.) in the laboratories of the Government College, Lahore (now in Pakistan), to investigate the exact nature of the post-nuclear body and the formation of the acrosome. The results of these investigations were published in the form of an abstract in the Proceedings of the 31st Indian Science Congress held at Delhi in 1944. Before, however, the detailed paper could be published partition of the country took place and all of us had to flee to this side of the border. Some years later, after we had established ourselves at Hoshiarpur, one of us (V. S. S.) prepared some more slides of the testicular material of the Guinea-pig obtained from the Medical College, Amritsar, and these were thoroughly studied by him and the senior author (G. P. S.) independently as well as jointly. The present paper is an account of the studies made both at Lahore and at Hoshiarpur.

Previous work

As such a lot of work has already been done on the spermatogenesis of mammals, it will not be possible for us to give here a complete account

of each and every paper available on the subject. An attempt will, however, be made to review as much of the literature as is relevant for this work.

Meves (1899), in his classical paper on the spermatogenesis of the guinea-pig has given a detailed review of the previous work on this subject. He describes a number of small granules (Kornchen) which are irregularly scattered in the idiosome (Idiozome) of the spermatocytes and the spermatids. This idiosome with granules lies adjacent to the nucleus. Each of these granules becomes enclosed in a vesicle (Blaschen) in the spermatid. Meves differs from Moore (1906) in that these vesicles do not necessarily arise before the appearance of granules in the idiosome. In the later spermatids the granules in the idiosome fuse together and ultimately give rise to a single bead which gets differentiated into two regions: the inner intensely black and the outer pale yellow in colour. This single differentiated bead grows to form the acrosome (Spitzenknopf) of the ripe sperm. When the outer and inner zones of the acrosome appear, the idiosome moves away and ultimately goes behind the nucleus. It then disappears or is sloughed off with the residual cytoplasm.

Meves has also given an extensive account of a complicated system of the central apparatus. He states that the centrosome, to begin with, is a dumb-bell-shaped body, situated in the idiosome of the primary spermatocytes. This body then comes out of the idiosome and consists of two distinct centrosomes in the spermatids. The proximal centrosome remains more or less connected with the nucleus, whereas the distal one moves towards the periphery of the cell. The ring-like centrosome, which is the product of the distal centrosome, moves down the axial filament and ultimately fuses with the base of the middle-piece of the ripe sperm. As a matter of fact the central apparatus is more complicated in the late spermatid than it is in the ripe spermatozoon.

A spindle-shaped vacuole has also been shown lying on the axial filament of the late spermatids. It moves downwards and ultimately disappears without performing any function. A 'Schwanzmanchette', which arises as a basket of threads in the region of the centrosomes, has also been described. This becomes a membranous tube which ultimately disappears apparently without serving any purpose.

Meves also mentions the chromatoid accessory body (Chromatoiden nebenkörper) which stains light red with Ehrlich's triple stain. This body lies in the cytoplasm on the side of the nucleus and near the idiosome. Meves differs from Moore (1906) who believes it to be a derivative of the extruded nuclear chromatin. Von Ebner's granules appearing in the cytoplasm of the later stages of spermateleosis are described as of fatty and osmiophilic nature.

In the mature spermatozoon, the tail is shown to be inserted on one side of the head and it has a protoplasmic bead on it. The posterior half of the nucleus in the ripe sperm is brighter than the anterior half.

Papanicolaou and Stockard (1918) have also traced the development of the idiosome in the germ cells of the male guinea-pig. According to them the idiosome in the primary spermatocytes is differentiated into two

regions: an outer blue-staining 'idioectosome' and an inner purple-staining 'idioendosome'. During the preparation for the first meiotic division the 'idioectosome' disappears and during the division itself the 'idioendosome' becomes scattered throughout the cytoplasm in the form of small granules which are named as 'idiogranulomes'. In the secondary spermatocyte appears a new 'idioectosome' containing the 'idiogranulomes' which, however, during the second meiotic division, are again scattered throughout the cytoplasm. In the reformed 'idioectosome' of the spermatid there is seen a clear vacuole, 'idiogranulotheca' surrounding each 'idiogranulome'. By rapid fusion the 'idiogranulomes' form a single large red-staining 'idiosphaerosome' enclosed in a large vacuole, the 'idiosphaerotheca' which in turn is formed by the fusion of the 'idiogranulothecae'. The 'idioectosome' which now begins to move away is renamed as the 'idiophthartosome'. In the meantime the 'idiosphaerosome' secretes a crescentic blue-staining 'idiocalyptosome' and is itself known from now onwards as the 'idiocryptosome'. In the ripe sperm the 'idiophthartosome' disappears along with the cytoplasm. The 'idiocryptosome' and the 'idiocalyptosome' together form a double cap, 'spermiocalyptra' for the sperm head. The 'idiosphaerotheca' persists through all the later stages and develops into a membranous cover for the cap and the head of the sperm and it is then known as the 'spermiocalyptrotheca'.

Gatenby and Woodger (1921) traced the origin of the Golgi apparatus on the middle-piece of the ripe sperm of *Cavia* and the development of the acrosome. Their description is mainly based on the preparations made by formalin-silver nitrate techniques of Cajal and Da Fano and long osmication process of Mann-Kopsch.

According to them the Golgi apparatus consists of an inner core of archoplasm and a cortical region of curved plates and rods called the dictyosomes. The appearance of the apparatus is, however, said to be sometimes reticular and sometimes homogeneous. Spherical mitochondria are scattered in the cytoplasm of the spermatocytes and the spermatids. A chromatoid body, similar to the one described by Meves (1899), has also been shown by them in the spermatocytes, spermatids and the division stages.

During the growth stages of the spermatocyte numerous tiny spheres known as the proacrosomic granules are differentiated within the archoplasm and Gatenby and Woodger believe that the Golgi elements or dictyosomes are associated with this differentiation. As already claimed by Papanicolaou and Stockard (1918) they also think, although they have not been able to establish it themselves, that the proacrosomic granules do not disintegrate during the division stages but retain their individuality and become scattered throughout the cytoplasm. These are subsequently distributed to the daughter cells and eventually come to lie within the re-formed archoplasm of the spermatid. Each proacrosomic granule, at this stage, is said to have a liquid-filled sphere around it and thus comes to lie in an archoplasmic vacuole. These proacrosomic granules lying in their respective archoplasmic vacuoles now come together and fuse gradually to form a fewer and larger granules. Finally, by this process of fusion,

is formed one large granule the proacrosome which is surrounded by a single archoplasmic vacuole. An inner darkly-staining area and a paler cortical zone are soon differentiated in this proacrosome. The Golgi apparatus complex now moves up and becomes applied to the anterior end of the spermatid nucleus. The proacrosome itself moves through the archoplasm, comes into close contact with the nuclear membrane and is now known as the acrosome. The archoplasmic vacuole still surrounds it except on one side where it is in contact with the nucleus and thus separates it from the archoplasm and the Golgi elements. The acrosome grows rapidly while the Golgi elements with the archoplasmic remains are drifting away from it, and develops by itself to attain its final form. The Golgi apparatus and the mitochondria now lie posterior to the nucleus and when the spermatid is elongating the former buds off a small part which ultimately takes up its position in the protoplasmic bead lying on the middle-piece of the mature sperm. Most of the mitochondria are grouped around the axial filament in the middle-piece. The remaining mitochondria, the main part of the Golgi apparatus and almost the entire cytoplasm are sloughed off the maturing sperm.

Ludford and Gatenby (1921) have shown that the 'Golgi apparatus in *Mus* and *Cavia* is a mere cortical layer plastered upon the surface of the centrosphere (archoplasm), separate dictyosomes or rods of any kind being apparently absent'. It has also been shown that the process of dictyokinesis is generally haphazard, at least in *Mus* and *Cavia* and is merely an unprecise sorting out of the Golgi elements between the two daughter cells.

During the dictyokinesis of *Mus*, Ludford and Gatenby have described the Golgi elements breaking away from the archoplasm and becoming scattered in the cytoplasm, while the archoplasm itself undergoes the process of fission. When the chromosomes are sorted out to the two daughter cells, the dictyosomes assemble together again to become attached to the archoplasm. The cause of dispersal of the Golgi elements is said to be the division of the centrosome.

During the early phases in the development of the spermatocyte of *Cavia*, on the other hand, the archoplasm to which the dictyosomes are attached, is shown to have remarkable frothing. Small bubbles appear on the periphery of the archoplasm and these disappear at the end of the diakinetic stage of the chromosomes. The dictyosomes are seen as distinct semilunar rods attached peripherally to the archoplasm, after the frothing disappears. The rest of the process of dictyokinesis is the same as in *Mus*.

Along with the Golgi elements the chromatoid body is also said to divide in equal parts during the process of dictyokinesis and each spermatid is shown to have a single chromatoid body, directly derived from that of the spermatogonium.

Rau and Brambell (1925), working on the living male germ cells of *Cavia* (also of rat and mouse) by Lewis method and with Janus green-staining, have confirmed the account of Gatenby and Woodger (1921). They have demonstrated the Golgi rods and dictyosomes but have failed to show the proacrosomic granules inside the archoplasm.

In 1929 Gatenby published a paper on the Golgi apparatus and vacuolar system of *Cavia*, *Helix* and *Abraxas* by intra-vital methods. This writer has shown that in the male germ cells there are a number of neutral red-staining vacuoles lying near, but not attached to, the Golgi dictyosomes. In some cases the vacuoles are in the archoplasmic area, at the periphery of which the Golgi dictyosomes lie, while in others they are extra-archoplasmic. These vacuoles are distinct from the Golgi dictyosomes, not only in the resting cells but also during the meiotic divisions when they are sorted out roughly into two equal parts. According to Gatenby these vacuoles are not consistently argentophilic, whereas the dictyosomes, from which these vacuoles are derived, are. Gatenby also gives an account of the work of Hirschler, Monne and Voinov on the male germ cells of lizard and grasshopper. These authors, as quoted by Gatenby, have also shown a vacuolar system, lying near, but distinct from the Golgi dictyosomes.

In the same year Gatenby and Wigoder (1929) recognized a new category of structures, the 'post-nuclear bodies' in the spermatogenesis of *Cavia cobaya* and other animals. It may be remarked that Gatenby (1918) had already made a mention of such bodies in the male germ cells of certain molluscs. In the ripe sperm of *Cavia cobaya*, Gatenby and Wigoder show an argentophilic band in the posterior region of the nucleus and they mention that 'no method except Da Fano picks out these bands in such an extraordinary manner'.

They have tried to trace back the history of this argentophilic band to the spermatocyte where the post-nuclear granules are shown to form the cortex of a vacuole in the vicinity of the Golgi apparatus but later on the vacuole disappears. In the spermatid these granules are grouped behind the nucleus and are described as 'elongate, hollow structures, which seem to expand till they touch and finally unite to form the solid covering behind the nucleus'. 'This expands further till it forms the cup-like structure, depicted in the spermatozoon'. They have, however, failed to give any test which can distinguish these granules from the other cytoplasmic inclusions like the Golgi bodies, mitochondria or the centrosomes.

Technique

It is a well-known fact that the morphology of a cell depends mainly on the technique employed. The different forms under which the Golgi apparatus of the same material has been described can be attributed to the different methods used. A good deal of time was, therefore, spent in trying almost all the techniques recommended by modern cytologists.

Chloroform was used as a light anaesthetic. The testes were quickly removed from the body of the animal and cut into small pieces with a razor blade in normal saline. These pieces were placed in different fixatives as quickly as possible.

The fixatives tried were those of Bouin, Champy, Da Fano, Flemming, Flemming-without-acetic, Kolatchev, Regaud and Zenker. The chilled Da Fano method recommended by Gatenby and Wigoder (1929) was also tried by cooling down the capsules containing fixative from 3° to 6° C.

Smears of the testicular material were also made in Flemming, Flemming-without-acetic, Bouin's and Da Fano's fixatives.

The mordant used was 4% or 5% iron-alum and the stain 0·5% hæmatoxylin. F.W.A. and Champy fixed sections were treated according to Kull's modification and stained with acid fuchsin. Da Fano's smears were at times toned in Manns' methyl blue eosin. Unstained F.W.A. and Champy sections were also mounted.

Feulgen's reaction was tried on sections and smears fixed in Flemming, Flemming-without-acetic, Champy and Zenker's fluids. For this reaction Flemming's fluid was found to be the best.

Breinl's preparations for the differentiation of the nucleus from the acrosome were also made. Both the Feulgen and Breinl preparations were found useful for determining the exact nature of the post-nuclear body.

As a result of our experiments with different techniques it was found that Flemming-without-acetic and Champy preserve all the cell inclusions perfectly.

Fresh material, teased out in a drop of 0·9% normal saline, on sterilized slides, was observed under oil immersion lens for short periods, both in reduced light and with full aperture.

Slightly osmicated material was also studied either in normal saline or in 2% osmic acid solution.

The manuscript of this paper was almost ready for the press when one of us (G. P. S.) had an opportunity to study the male germ cells of the guinea-pig under the phase contrast microscope. In general, this study also confirmed the results obtained from the fixed material.

Observations

Spermatogonia: The spermatogonia in the guinea-pig are fairly large cells, usually found near the periphery of the follicles (Plate I, Fig. 1). In each of them there is a vesicular nucleus which contains inside it not only fine chromatin granules but also big chromatin masses. Distributed all over the cytoplasm are fine granules which appear pale yellow with iron-hæmatoxylin stain. These are the mitochondria. The Golgi elements exist in the form of a juxta-nuclear mass of darkly-staining granules which are definitely bigger in size than the mitochondria. In the fully grown spermatogonia the Golgi elements also become spread throughout the cytoplasm (Plate I, Fig. 2).

During the spermatogonial metaphase (Plate I, Fig. 3) the chromosomes arrange themselves at the equator of the spindle which is a fibrillar structure. At each pole of the spindle there is a sharply-staining granule, the centrosome, but it is completely devoid of the astral rays. The cytoplasm reveals fine granules which are the mitochondria. It has not, however, been possible to demonstrate the Golgi elements with certainty during the spermatogonial divisions.

Primary spermatocytes: The primary spermatocytes are definitely larger cells than the spermatogonia, their nuclei also being larger (Plate I, Fig. 4). In this particular cell the chromosomes have already been

differentiated in the nuclear area. The mitochondria, which are scattered throughout the cytoplasm, are small and granular. The Golgi elements, at this stage, have a distinct tendency to come together to form bigger granules. Some of these big Golgi granules have already collected together to be in the localized condition which is so prominent in the secondary spermatocytes and the spermatids.

The primary spermatocytes in metaphase are quite common (Plate I, Fig. 5). The spindle area stands out from the general cytoplasm by being less darkly stained than the latter and is presumably of a different consistency. The spindle fibres are also clearly visible. At each pole of the spindle is a small but distinct centrosome. The Chromosomes appear at the equator of the spindle as a deeply-staining mass in which the individual elements cannot be clearly made out. The finely granular mitochondria remain scattered throughout the cytoplasm. Two Golgi granules (one big and the other small) are also seen separating in the cytoplasm.

In the telophase I (Plate I, Fig. 6) the chromosomes are grouped at the two poles of the spindle. The centrosomes are hardly distinguishable in these stages. The mitochondria still remain spread throughout the cytoplasm but some of the Golgi elements can now be clearly seen within the spindle area also. As the cell divides both the mitochondria and the Golgi elements are almost evenly distributed to the two daughter cells.

Secondary spermatocytes: Each resulting secondary spermatocyte is again smaller than the primary (Plate I, Fig. 7). While the mitochondria in it remain distributed throughout the cytoplasm, most of the Golgi elements have collected together to be in the typical localized condition. At this stage one can see a number of small osmiophilic Golgi granules embedded in a spherical or ovate osmiophobic area which appears to be nothing but a denser portion of the cytoplasm. This is the idiosome. The rest of the Golgi granules still remain scattered in the cytoplasm and some of these have been referred to as the chromatoid bodies by the previous workers.

During the second meiotic division the chromatin of the nucleus gives rise, as usual, to the regular chromosomes. The centrosomes become active once again and they take up their position at the two poles of the spindle which reveals faintly staining spindle fibres (Plate I, Fig. 8). Like the mitochondria, the Golgi elements also get dispersed in the cytoplasm at this stage. Some of the Golgi elements can even be seen lying on the spindle fibres between the two groups of chromosomes (Plate I, Figs. 8 and 9). After the process of nuclear reconstruction the cell divides and we thus get two daughter cells—the spermatids. During this division also the mitochondria and the Golgi elements are sorted out, more or less evenly, to the two spermatids thus formed.

It is important to note that some of the secondary spermatocytes do not divide for a long time even after the nuclei of the two daughter spermatids have been completely formed in them. One such example is illustrated in Figure 10, Plate I.

Spermatid: The earliest spermatid is a comparatively small cell with a compact nucleus (Plate I, Fig. 11). Most of the Golgi elements in it have

once again come to lie in the special chromophobic and denser area in the cytoplasm known as the idiosome. The rest of the Golgi elements, just like the mitochondria, remain scattered throughout the cytoplasm.

Spermateleosis: The process of spermateleosis is heralded by a distinct tendency of the Golgi elements to come together. This results in the formation of a fewer and bigger Golgi granules not only in the idiosome but also in the cytoplasm (Plate I, Figs. 11 and 12). The fusuion of the Golgi granules in the idiosome, however, continues till only a single big Golgi granule is produced (Plate I, Figs. 13 to 17). This is situated almost in the centre of the idiosome (Plate I, Fig. 17). Soon after its formation it becomes surrounded by a clear vacuole which gradually increases in size as the idiosome moves towards one side (Plate I, Figs. 18 to 21). The single Golgi granule now moves through the vacuole and comes in intimate contact with the nuclear membrane (Plate I, Fig. 22). This Golgi granule may, at this stage, be termed as the acrosome. To begin with, it is a small structure (Plate I, Fig. 22), but it increases in size gradually (Plate I, Figs. 23 and 24). The nucleus which had been almost perfectly spherical till this stage now grows under the vacuole in the form of a conical projection with the acrosome situated at its tip (Plate II, Fig. 25). The acrosome in all these stages has been a big darkly-staining granule but from now onwards it becomes differentiated into two regions—an inner darkly-staining and an outer lightly-staining (Plate II, Figs. 26 to 31).

Simultaneously when the single Golgi granule, which ultimately gives rise to the acrosome, is being formed in the idiosome another equally big Golgi granule appears to pass out of the idiosome into the cytoplasm (Plate I, Figs. 18 and 21). This seems to be the homologue of the accessory body described in a number of mammals by Gresson and Zlotnik (1945). From this it appears to us that all the Golgi elements in the idiosome are not used up in the formation of the acrosome. This is further proved by the presence of the Golgi granules in a small portion of the idiosome which is separated from the main mass of the idiosome as depicted in Figure 19, Plate I. It is also quite likely that the small portion of the idiosome with Golgi elements in it may be the equivalent of that portion of the Golgi apparatus complex which, according to Gatenby and Woodger (1921), gives rise to the Golgi apparatus on the middle-piece of the ripe sperm. On the other hand, the portion of the idiosome without Golgi granules may be the subspherical body which, according to Gresson and Zlotnik (1945), separates at this stage from the Golgi apparatus complex of the Rabbit. In any case, after the acrosome has been formed, the remains of the idiosome with or without the Golgi elements drift backwards from the anterior end of the nucleus and in this study they have all been labelled as the Golgi remnants (Plate I, Figs. 19 to 24 and Plate II, Figs. 25 to 33).

At this stage one can also see an axial filament growing out from a small granule lying in the cytoplasm. This granule is the proximal centrosome (Plate II, Figs. 31 to 33 and 35 to 37). Soon afterwards the distal centrosome also makes its appearance just near the proximal and it is in the form of a ring which encircles the axial filament (Plate II, Fig. 38) It appears that, when the spermatid begins to elongate, the originally

single centrosome of the early spermatid divides into two—one forming the granular proximal centrosome and the other ring-like distal centrosome. The latter now begins to travel down the axial filament (Plate II, Fig. 39 and Plate III, Fig. 40) till ultimately it takes up its position at the posterior end of the sperm middle-piece. In the meanwhile a somewhat darkly-staining area of the cytoplasm is differentiated immediately behind the elongating nucleus. This is the 'manchette' which forms the lateral boundaries of the middle-piece while the two centrosomes form its anterior and posterior boundaries (Plate II, Fig. 37 and Plate III, Figs. 40 to 42). The mitochondrial granules which are included in this area now become darkly-staining (Plate III, Fig. 41). It seems that by a process of fusion they form bigger and prominent mitochondrial granules which ultimately arrange themselves around the axial filament to form the middle-piece of the sperm (Plate III, Figs. 43 to 45 and 47 to 49). The rest of the mitochondria along with the Golgi remnants and also those Golgi granules which did not assemble in the idiosome in the earlier stages remain lying in the residual cytoplasm (Plate III, Figs. 43 to 45). All these apparently useless inclusions will now either degenerate or will be sloughed off with the residual cytoplasm during the final maturation of the sperm. Some of the Golgi elements at this stage are, according to a number of previous workers, converted into fat but we are not in a position to say anything definitely about it as no special tests were performed for detecting fat in our preparations.

During all these changes the acrosome which had earlier taken its position at the anterior end of the elongating nucleus can be clearly seen spreading itself gradually like a cap along the sides of the nucleus till ultimately it covers roughly more than half of the sperm nucleus (Plate II, Figs. 34 to 39 and Plate III, Figs. 40 to 42).

Spermatozoon: The sperm of the guinea-pig (Plate III, Figs. 46 to 50) reveals almost the same structure as that of the typical mammalian sperm. It has a broad head and a long tail with a small but distinct neck in between them.

The head consists of a nucleus and an acrosome. The acrosome which covers roughly more than half of the sperm nucleus appears to be in the form of a broad cap-like structure in surface views (Plate III, Figs. 48 to 50) but in side views it seems to be produced into a conical projection (Plate III, Figs. 46 and 47). It is often differentiated into two regions which were also noted earlier during spermateleosis. The outer of these is lightly-staining and the inner deeply-staining. The nucleus is more or less an oval body with a flattened posterior border. Its anterior half which is covered over by the acrosomal cap appears to be darker than the posterior uncovered portion (Plate III, Figs. 48 and 49).

The tail is attached to the posterior end of the nucleus. The neck which comes in between the head and the tail is bounded on both sides by two fine threads (Plate III, Figs. 47 to 49). On the middle-piece is very often seen a small portion of the cytoplasm containing the Golgi elements (Plate III, Fig. 46). This is the protoplasmic bead which seems to travel down the middle-piece till it is finally lost during the passage of the sperms

through the sperm ducts. Distinct mitochondria can also be clearly seen forming the middle-piece of the sperm (Plate III, Figs. 43 to 45 and 47 to 49).

The so-called post-nuclear body shown at the posterior end of the nucleus of the ripe sperm of *Cavia cobaya* by Gatenby and Wigoder (1929) was never seen in any of the numerous preparations made by us. In Feulgen's and Breinl's preparations it has been clearly seen that the post-nuclear body of Gatenby and Wigoder (1929) is in reality the dense posterior region of the nucleus itself and is not a separate body as urged by them (Plate III, Fig. 50). In some of our Da Fano's smears, however, silver is deposited on the posterior part of the nucleus of the ripe sperm and this may correspond to the so-called post-nuclear body of Gatenby and Wigoder (1929).

During the study of the living material it was observed that the sperms move by means of the lashing movement of the tail and they maintain their motility for a considerably long time. They often move in groups of three or four with their heads one above the other. These sperm aggregates give the impression as if they constitute the conjugate sperms. Sperms in side views reveal that the heads are convex on one side and concave on the other.

Discussion

Golgi elements: It will be recalled that in the earliest spermatogonia of the guinea-pig the Golgi elements exist in the form of a juxta-nuclear mass of darkly-staining granules which are definitely bigger in size than the mitochondria. In the fully grown spermatogonia, however, the Golgi elements, like the mitochondria, become spread throughout the cytoplasm. In the primary spermatocytes the Golgi elements reveal a distinct tendency to come together to form bigger granules. Some of these big Golgi granules now collect together to be in the localized condition which is so prominent in the secondary spermatocytes and the spermatids.

In its localized form the Golgi apparatus has very often been described as a network. In fact it was the general opinion of Golgi, his pupils and many other workers that the Golgi apparatus in the cell was characterized by its reticulate form. That the reticulate or network-like appearance of the Golgi apparatus is produced as a result of certain fixatives is admitted even by Gatenby and Woodger (1921), according to whom, the Golgi apparatus in *Cavia* with formalin-silver nitrate techniques 'either appears as a reticulum, or the whole cortex of the apparatus reduces the silver, and then appears as homogeneous: with Mann-Kopsch techniques the individual dictyosomes are often very clearly marked'. In regard to the Golgi nets it will be refreshing to quote what Nath said in 1944. 'For many years since the discovery of the 'apparato reticolare interno' by the silver method, nobody seems to have questioned the validity of Golgi networks. The various modifications of the original silver method employed by Golgi were followed by the long osmication methods, which are, at best, only slightly less unsatisfactory. There is no doubt that the Golgi material has a marked affinity for silver and osmium, and further

it has been made abundantly clear that the Golgi elements are often held in chains or are closely aggregated in a juxta-nuclear position. When silver nitrate or osmium tetroxide is reduced to metallic silver or osmium respectively, the reduced particles seem to come down like a shower and are deposited not only on the surface of and in the interior of the Golgi elements, but also in the narrow spaces between them. The result is a network! . . .'

Nath (1944) continues—'It is pertinent to ask: Have ever Golgi nets been demonstrated by methods not involving reduction of silver nitrate or of osmic acid for long periods? To the best of my knowledge they have never been. On the contrary, various miscellaneous methods (e.g., Champy or Flemming-without-acetic and iron-hæmatoxylin) have invariably demonstrated discrete Golgi elements in a large variety of cells. I have never observed any nets in the course of my studies on male and female germ cells of various animals, even in silver and osmium preparations; and I have always doubted the validity of the reticulate structure of the Golgi apparatus.'

Similarly Bourne (1951) says that ' . . . grains of reduced silver seem to be composed fundamentally of a network structure. The granules of silver in a photographic emulsion even under the high power of the ordinary microscope appear to be homogeneous, but when they are examined with an electron microscope, magnifying them by 25,000 diameters, they may be seen to be networks, made up of threads, some of which are only five atoms thick (Plate II, Fig. 2). The type of network can be varied according to the developer used. Hydroquinone produces coarse threads, whereas metol produces fine threads. With some other developers the network becomes a sort of fluffy mass. The form of the Golgi network also varies according to the time of development and the type of developer used.'

It is now generally believed that the localized Golgi apparatus consists of discrete Golgi elements which are associated with a slightly deep-staining body known by the name of 'idiosome' or 'archoplasm'. The Golgi material of the spermatocytes and the spermatids of *Cavia*, according to Gatenby and Woodger (1921) is in the form of curved plates and rods called the dictyosomes which surround the archoplasm. These observations have also been confirmed by Rau and Brambell (1925) who carried out investigations on the living spermatocytes and early spermatids of the guinea-pig by the Lewis method and with Janus green-staining. On the other hand, we have clearly shown that the Golgi elements in the male germ cells of the guinea-pig are in the form of small osmiophilic granules, most of which become embedded in the idiosome of the secondary spermatocytes and the early spermatids. Even under the phase contrast microscope, while we could easily see these Golgi granules embedded in the idiosome, we could not make out any such cortex of banana-shaped bodies or the dictyosomes round the idiosome as has been described by the above-mentioned authors. Our preparations made with Flemming-without-acetic and stained with 0·5% iron hæmatoxylin show clearly that the large dictyosomes figured by Gatenby and Woodger (1921) at the

periphery of the idiosome are artifacts produced by Cajal and Mann-Kopsch techniques employed by these authors. As already pointed out, in the silver-nitrate or long osmication techniques, on account of the deposition of the reduced particles of silver or osmium not only on the Golgi granules but also in the narrow spaces between them, the Golgi granules situated at the periphery of the idiosome may join together to form rods, crescents and dictyosomes. Indeed Meves (1899) in his classical work on this material has actually figured granules and not rods in the idiosome.

The granular Golgi elements have also been described in dog by Bell (1929) who at no stage was able to see them in the shape of crescents or dictyosomes. He has clearly mentioned that 'these granules are undoubtedly the homologue of the Golgi apparatus described for the guinea-pig by Gatenby and Woodger (1921) but at no time do they assume a crescentic shape like those of *Cavia*'. Even Gatenby and Beams (1935), working with the human material, admit that a cortex of osmiophile or argentophile material is found only in those preparations which are made by the Golgi apparatus methods. They further state that 'sometimes the osmiophile material is smooth, sometimes crenated, sometimes raised into beads and sometimes even batonette-like in arrangement'. Gresson (1942) 'concludes that the Golgi material of the developing male germ cells of the mouse is in the form of rods and granules. The Golgi elements are, however, small and closely packed together around the archoplasm, making observation of their shape extremely difficult'. Some similar observations have also been made by Gresson and Zlotnik (1945 and 1948). In our opinion, however, the dictyosomes, batonettes and rods, etc., are all artifacts produced by the action of certain fixatives. The real form of the Golgi apparatus is just granular. In fact the proacrosomic granules which, according to Gatenby and Woodger (1921), are differentiated within the archoplasm during the later growth stages of the spermatocyte are really the Golgi elements.

Idiosome: It has been shown earlier that most of the Golgi granules in the secondary spermatocytes and the early spermatids of the guinea-pig become embedded in a slightly deep-staining, rounded or oval body lying near the nucleus. This body has been referred to as idiosome by Papanicolaou and Stockard (1918), idiozome by Meves (1899), sphäre by Niessing (1896), accessory corpuscle by Brown (1885), archiplasm by Benda (1896-7) and archoplasm by Moore (1906) and Gatenby and Woodger (1921).

Formerly it was thought that the idiosome was a structure distinct from the classical Golgi material (osmiophilic) though the two are usually closely associated with each other. But it is now generally believed that this body forms a definite part (osmiophobic) of the classical Golgi apparatus (osmiophilic), the latter forming the wall and the former filling up the interior.

Gatenby and Woodger (1921), Gatenby and Beams (1935), Gresson (1942) and Gresson and Zlotnik (1945) have all described the idiosome and its cortex as respectively the chromophobic and chromophilic parts of the Golgi apparatus. As, however, we have already shown that the curved

plates and rods which, according to these authors, form the chromophilic cortex of the idiosome are artifacts produced by the techniques employed by them, it appears to us that the granules embedded in the idiosome represent the chromophilic or osmiophilic part and the idiosome itself represents the chromophobic or osmiophobic part of the Golgi apparatus.

A reference may also be made here to the 'Pre-substance Golgi system' theory of Hirsch (1939) according to whom the Golgi bodies of the cell are not always duplex in structure. He states that there is some 'pre-substance' of the Golgi apparatus, probably of mitochondrial origin, which does not show differentiation into osmiophilic and osmiophobic substances and is able to build up nets. Each piece of the 'pre-substance' gradually develops the double structure by the absorption and concentration in its interior of water and water soluble substances and it is then referred to as a 'Golgi system'.

It is significant to note that the presence of a juxta-nuclear mass of Golgi granules in association with the mitochondria in the spermatogonia of the guinea-pig lends support to Hirsch's theory.

Dictyokinesis: There is no unanimity about the details of the division of the Golgi elements during the meiotic stages. The process of division which is usually known as dictyokinesis is generally haphazard. It does not require any sort of fission of the individual elements as is seen during karyokinesis but is merely an unprecise sorting out of the Golgi elements among the daughter cells.

Duesberg (1920) mentions that the Golgi material in the opossum does not break up into granules until the anaphase, when it forms one or more clumps situated between the chromosomes. Similarly Gresson (1942) states that in the mouse 'the Golgi material remains in a single clump and is separated passively into two smaller groups with the division of the cell'. On the other hand, the whole of the localized Golgi apparatus of *Mus* and *Cavia*, according to Ludford and Gatenby (1921), divides into two parts which pass with the centrioles to opposite poles of the spindle and break up into separate Golgi bodies or dictyosomes. These scatter through the cell during the metaphase and again aggregate into a localized mass in the daughter cells.

Papanicolaou and Stockard (1918) claim that the idiogranulomes, which are really the Golgi elements, retain their individuality during the cell division and ultimately become sorted out to the two daughter cells. Meves (1899), Niessing (1896) and Moore (1906) have all failed to follow these granules during the division stages but they believe that these granules soon become visible after the idiosome is reformed in the daughter cells. Gatenby and Woodger (1921) also follow the account of Papanicolaou and Stockard (1918), though they have not observed it themselves. They have given a diagrammatic figure illustrating the phenomenon of mitosis according to their own view. Around each mitotic aster they have shown groups of approximately half of the Golgi elements or dictyosomes which break away from the archoplasm by its disintegration in the earlier stages.

According to Gatenby and Beams (1935) the dictyokinesis during the spermatogenesis of man 'was of a somewhat unexpected type' because the idiozome or archoplasm during the early prophases broke up and the osmiophile cortex separated into a cloud of granules and not into curved rods or batonettes. This certainly supports our claim that the form of the Golgi apparatus is essentially granular and that the batonettes and curved plates, etc., are mere artifacts.

During the meiotic divisions of the guinea-pig we have clearly shown that the Golgi granules become dispersed and lie not only in the vicinity of the spindle but also in the spindle area itself. It is presumed that the idiosome breaks up in the early stages of division and the individual Golgi elements in it then become spread all over to be sorted out almost equally to the two daughter cells where they again become localized in the reformed idiosome. The Golgi material during these stages was never observed in the form of clumps as described by Gresson (1942). It is believed that such clumps may be due to faulty technique. The remarkable frothing described in the idiosome of the spermatocytes of *Cavia* by Ludford and Gatenby (1921) was also not observed.

Acrosome: As has been said above most of the Golgi granules, after the two meiotic divisions, again become embedded in the idiosome of the early spermatid. At this stage the Golgi granules reveal a distinct tendency to come together and this results in the formation of a fewer and bigger Golgi granules. The process of fusion of the Golgi granules in the idiosome, however, continues till only a single big Golgi granule is formed. This is situated almost in the centre of the idiosome. Soon after its formation it becomes surrounded by a clear vacuole which gradually increases in size as the idiosome moves towards one side. The single Golgi granule now moves through the vacuole and comes in intimate contact with the nuclear membrane. Henceforth this Golgi granule is termed as the acrosome which is a small structure, to begin with, but increases in size gradually. It then becomes differentiated into two regions—an inner darkly-staining and an outer lightly-staining. As the spermatid begins to elongate the two regions of the acrosome become spread over the anterior end of the nucleus like a cap which, in the ripe sperm, can be seen covering more than half of the elongated nucleus.

As early as 1899 Meves also recognized a number of granules (Kornchen) embedded in the idiosomic body. He showed that the clear vesicles round the granules develop later and not before the appearance of the granules as described by Moore (1906). Duesberg (1908) like Moore (1906) shows the vacuoles arising earlier than the appearance of the granules in the idiosome. On the other hand, we could not make out any such vacuole round each Golgi granule at this stage.

Duesberg (1908) traces the origin of the acrosome of rat to the granules which develop in the vacuoles. Papanicolaou and Stockard (1918) also derive the acrosome by the fusion of the granules in vacuoles (their idiogranulomes in idiogranulothecae) which are present in the idiosome (their idioectosome). Gatenby and Woodger (1921) describe the formation of the acrosome by the fusion of the proacrosomic granules which, according

to them, are differentiated in the archoplasm during the later growth stages of the spermatocyte.

It, therefore, becomes an admitted fact that the acrosome owes its origin to the Golgi apparatus. There is, however, difference of opinion as to whether the Golgi apparatus secretes the acrosome or itself gets transformed into it. Gatenby (with Woodger, 1921 and with Beams, 1935) believes that the acrosome is formed by the fusion of the proacrosomic granules which, in their turn, are differentiated in the archoplasm perhaps under the influence of the surrounding dictyosomes. Gresson (1942), though he could not demonstrate the proacrosomic granules, also seems to believe in the secretory hypothesis as he states that 'there is little doubt that the acrosome is formed under the influence of the Golgi material. It is probable that it arises from proacrosomic granules which run together in a similar manner to those of the guinea-pig'.

Gresson and Zlotnik (1945) further show that the Golgi material is not only associated with the formation of the proacrosome but 'is also concerned with the secretion of a substance inside the archoplasmic vacuole, which at a later stage takes part in the formation of the acrosome'.

On the other hand, the observations of Bell (1929) on the spermatid of dog coupled with our own findings in the guinea-pig definitely suggest that the proacrosomic granules of Gatenby and Woodger (1921) are the Golgi elements themselves and not the secretory products of the Golgi dictyosomes which have been shown by us to be artifacts (vide supra). Indeed the figures of Meves (1899) for the spermateleosis of the guinea-pig clearly show that the acrosome is directly formed by the fusion of the Golgi granules which cannot be the secretions at all as there are no dictyosomes shown in his figures. Our observations on the guinea-pig are strongly supported by the recent work of Nath and Bhatia (1953) on *Lepisma* sperm, according to whom, the acrosome is formed by the direct fusion of the Golgi vesicles and is not a secretory product thereof, as described by Bowen (1924). Similarly Sharma and Malik (1953) have also shown clearly that in the lice, *Pediculus capitis* and *Pediculus corporis* there is a single Golgi granule, to begin with, which during the late stages of spermateleosis is directly transformed into the acrosome. For the direct origin of the acrosome reference may also be made to Nath (1932 and 1942) and Sharma (1944 and 1950).

Accessory or *Chromatoid body*: Gatenby and Beams (1935) were the first to describe an accessory body in the human spermatocyte. They have neither recorded its behaviour during meiosis nor its presence in the spermatid. They, however, felt that many of these accessory bodies were simply parts of the spermatogonial Golgi elements which failed completely to assemble together. Gresson (1942) also recognized a Golgi granule in the neck region of very late spermatids and ripe spermatozoa. He states that 'not only was this substance traced from its origin, from the Golgi material which had moved away from the growing acrosome, but its appearance and reactions in champy-kull, Aoyama, and Kolatchev sections leave little doubt that it is composed of Golgi substance'. Gresson and Zlotnik (1945) believe that the accessory body has been seen in the male

germ cells of a number of mammals and has been described as a chromatoid body. According to them the accessory bodies originate from the localized Golgi material of the spermatocytes and the spermatids. These do not divide during the meiotic divisions but each spermatid receives at least one. Finally an accessory body is included in the neck region of the ripe sperm. It will be remembered that we also described the passing out of a big Golgi granule from the idiosome when most of the Golgi granules in it had fused to form the fore-runner of the acrosome and we compared it to the accessory body described by Gresson and Zlotnik (1945 and 1948). We further feel that some of those Golgi granules also which do not come together to be in the localized condition and remain dispersed throughout the cytoplasm of the spermatocytes and the spermatids may have been labelled as chromatoid bodies by the earlier workers. That the chromatoid body, described by Bowen (1924), Gatenby and Mukerji (1929) and Mukerji (1929), is only that part of the Golgi apparatus which does not merge into the acrosome has also been recently proved in this laboratory by Nath and Bhatia (1953). See also Nath (1932, 1937 and 1942).

Middle-piece protoplasmic bead: Retzius (1909) figures a small bead of protoplasm on the middle-piece of the spermatozoa of several mammals including *Cavia*. His figures show that the bead is not always present in the same position in different animals and that in some it is absent altogether. Gatenby and Woodger (1921) show it immediately behind the nucleus. According to them a small part of the Golgi material with archoplasm becomes separated from the main mass in the elongating spermatid and it ultimately takes up its position in the protoplasmic bead of the middle-piece. As pointed out by Rau and Brambell (1925) we also believe that the bud from the Golgi remnant is given off at an earlier stage than that described by Gatenby and Woodger (1921) and that it becomes separated from the Golgi remnant before it moves away from the vacuole surrounding the big Golgi granule which is destined to form the acrosome (Plate I, Fig. 19). It is, however, very difficult to say that the Golgi granules noted in the protoplasmic bead are derived from the same bud, as urged by Gatenby and Woodger (1921) and later confirmed by Gresson (1942). In our opinion, the protoplasmic bead is merely a cytoplasmic structure. When the residual cytoplasm is being sloughed off a small part of it remains sticking to the middle-piece of the ripe sperm. As the residual cytoplasm contains not only the Golgi remnants but also those Golgi granules which did not assemble together in the earlier stages, it is quite likely that some of those Golgi granules also become included in the protoplasmic bead along with the small part of the residual cytoplasm forming it. Gresson and Zlotnik (1945) have shown that the Golgi material after the formation of the acrosome moves to the posterior part of the spermatid. There it breaks up into two parts one of which gives rise to the argentophil granules contained in the protoplasmic bead. They further show that the protoplasmic bead moves down the middle-piece when the sperms are in the epididymis and is finally eliminated. Some similar observations have also been made in this country by Mukherjee and Bhattacharya (1949), according to whom, the maximum number of spermatozoa with protoplasmic

bead in the neck region were found in the caput epididymis of all the species of farm animals studied by them. The cauda epididymis contained the maximum number of spermatozoa with protoplasmic bead on the middle-piece while in the ampullæ the percentages of spermatozoa with protoplasmic beads were minimum and hardly exceeded 2%. They also believe that the spermatozoa with protoplasmic beads are still immature.

Post-nuclear body: Gatenby and Wigoder (1929) were the first to describe the post-nuclear granules in the male germ cells of *Cavia*. According to them, these granules, to begin with, can be seen in the neighbourhood of the Golgi apparatus of the spermatocytes forming the cortex of a vacuole which, however, disappears later on. In the spermatid these granules are situated behind the nucleus and have been described as 'elongate, hollow structures, which seem to expand till they touch and finally unite to form the solid covering behind the nucleus'. 'This expands further till it forms the cup-like structure depicted in the spermatozoon.' In the ripe sperm they show an argentophile band (the post-nuclear cup) on the posterior part of the nucleus, stressing that 'no method except Da Fano picks out these bands in such an extraordinary manner'.

Gatenby and Beams (1935), though they have not been able to follow the development of these granules through the different stages of spermatogenesis, claim that the human testicular material also contains the post-nuclear bodies. They have depicted these structures only in their diagrammatic figures and none of their diagrams drawn from actual preparations shows these structures except their Fig. 26 in which they have given just an indication of the post-nuclear cap. They admit that 'both the origin and the subsequent history of these sharply impregnated structures are somewhat difficult to make out . . .' They further state —'The earliest stage we can trace the rudiment back is shown in Fig. 9, Pl. 2, where in many cases a very sharp membrane (PNC) is found at the back of the nucleus. Between the stages in Figs. 9 and 10, Pl. 2, we have studied many examples of this growing membrane, but in other cells it is not demonstrable (Fig. 28, Pl. 4)'. Even in the absence of the requisite stages Gatenby feels convinced that the final form of these bodies 'is brought about by a creeping up and growth of such material, probably of lipoidal nature'. Gatenby and Beams (1935), however, confess that they are not certain 'whether it is ever a separate rudiment in the cytoplasm of the spermatid, or merely a thickening on the nuclear membrane'. This is attributed by them to the fact that they did not have any Da Fano silver nitrate preparation and that 'it is in this material that the post-nuclear bodies of *Cavia* are clearest'.

Zlotnik (1943) described a nuclear ring surrounding the nucleus of the late spermatid and the sperm of the dog and the cat. He believed that the post-nuclear cap was formed by its widening posteriorly. Gresson and Zlotnik (1945), after a thorough examination by one of them (I.Z.) of the sperms of the animals in which the post-nuclear cap is clearly visible, conclude 'that the widening of the nuclear-ring never reaches the extreme posterior end of the sperm-head; a narrow light space being present between the wide band which comes down from the nuclear-ring and the

black posterior edge of the head. This argentophil posterior edge of the head is traced back to a time when the nuclear-ring is more conspicuous than at any other stage, and a black granular ring, often interrupted, forms the posterior end of the nucleus of the late spermatid. This new structure is called the posterior ring, and it is suggested that it may be formed from argentophil granules scattered around the posterior region of the nucleus at an earlier stage. The origin of these granules is not clear; it is probable that they may be identical with Gatenby's and Woodger's post-nuclear body, on the other hand some of the granules at least may originate from the Golgi material. The granules make their first appearance in the dog and cat spermatids very soon after the Golgi material moves away from the posterior part of the already elongate nucleus, while in the rabbit they are seen at a much earlier stage, at the time when the archoplasmic vacuole begins to lift up the Golgi material. The suggestion is made that not all of these granules form the posterior ring, but only those which are attached to the nuclear membrane'.

Regarding the silver methods (by the application of which the so-called post-nuclear body is said to be clearly demonstrated) it may be mentioned that one should not depend merely on these for deciding the nature of any particular structure. The draw back in these and long osmication methods is that they blacken mitochondria, nuclear membrane and several other structures in the cell which are not related to the Golgi apparatus at all. It, therefore, appears that the granules of silver and osmium can settle down on many kinds of surfaces. Friend (1936), while working on the sperms of the British Muridae, discovered an asymmetrical deeply-staining area in the posterior region of each sperm nucleus he examined, and it gave the characteristic Feulgen's reaction. He named it as the 'dense posterior region' and remarked that in position it agreed with Gatenby's 'post-nuclear body'. By employing Feulgen's reaction on smears of the testicular material of the guinea-pig it has been confirmed by us that the so-called post-nuclear body is in reality the dense posterior region of the nucleus itself and not a separate body (Plate III, Fig. 50). Neither in Da Fano's (chilled) nor in any other preparation were the post-nuclear granules observed at any stage of spermatogenesis of the guinea-pig. In some of our Da Fano's smears, however, silver was deposited on the posterior part of the nucleus of the ripe sperm. This is identical with the post-nuclear cup of Gatenby and Wigoder (1929) and it clearly explains how these authors, depending mainly on the capricious silver nitrate technique, have been led to establish a new category of structures. In view of the characteristic Feulgen's reaction we are inclined to the view that the post-nuclear body is nothing but a part of the nucleus, probably containing most of the dense chromatin material.

Recently Nath and Bhatia (1953) have also confirmed that the 'post-nuclear body' of Gatenby and Mukerji (1929) and Mukerji (1929) in *Lepisma* is in reality the acrosome as shown earlier by Bowen (1924).

Centrosomes: The centrosomes embedded in the idiosome, as described by some of the earlier workers, were never observed in the present study. They were clearly seen at the time of divisions in the form of small granules

situated one at each pole of the spindle. In some of the spermatocytes and early spermatids a small darkly-staining granule surrounded by a clear area was also seen and this was most probably the centrosome. As the spermatid begins to elongate an axial filament can be seen growing out from a darkly-staining granule situated at the posterior end of the nucleus. This is the proximal centrosome. The distal centrosome, which soon appears near it, is in the form of a ring encircling the axial filament. It appears that the originally single centrosome of the early spermatid divides into two but we have never observed this division. Gatenby and Beams (1935) believe that the axial filament of the human sperm grows out jointly from the two bodies which are formed as a result of the division of the single centrosome. While the proximal granular centrosome remains in the vicinity of the posterior pole of the nucleus, the distal ring-like centrosome travels down the axial filament and ultimately takes up its position at the distal end of the middle-piece.

Wodsedalek (1913) has described that the ring centriole in the spermatid of the pig sometimes divides but usually becomes spherical and is finally lost with the residual cytoplasm. We have not, however, seen the distal or proximal centrosome dividing or being lost and thus our observations are in complete accord with those of Gatenby and Beams (1935) and Gresson and Zlotnik (1945 and 1948).

Mitochondria: According to Gatenby and Woodger (1921) the mitochondria in the spermatogonia of the guinea-pig surround the archoplasm, to begin with, but become dispersed throughout the cytoplasm later on. Gatenby and Beams (1935) also claim that in man these are situated mostly near the Golgi apparatus. Gresson (1942), however, states that in the mouse there are very many mitochondria near the nucleus, the periphery of the cell being almost clear. According to Gresson and Zlotnik (1945) the mitochondria in the pig and the sheep are dispersed throughout the cytoplasm, in the dog they form a horse-shoe and in the other animals studied by them they are in plenty in the neighbourhood of the nucleus. Gresson and Zlotnik (1948) state that the mitochondria in the spermatogonia of bull surround the nucleus and are most numerous near the Golgi material. In the primary spermatocytes the mitochondria, according to most of the previous workers, are found near the Golgi material, to begin with, but become spread throughout the cytoplasm gradually. In contrast to these observations we have noticed in our present investigations that the mitochondria remain dispersed throughout the cytoplasm not only in the spermatogonia but also in the spermatocytes and the spermatids. During the mitotic as well as meiotic divisions these are distributed almost equally to the two daughter cells. In the late spermatids the mitochondrial granules which are included in the area enclosed by the manchette become darkly-staining. It appears that by a process of fusion they form much bigger and prominent mitochondrial granules which ultimately arrange themselves around the axial filament to form the middle-piece of the ripe sperm. The rest of the mitochondria which remain lying in the residual cytoplasm either degenerate or are sloughed off with the residual cytoplasm during the final maturation of the sperm.

Manchette: In the guinea-pig the manchette was first seen in the late spermatid as a somewhat darkly-staining area of the cytoplasm immediately behind the elongating nucleus. As stated above the mitochondria also in this area become darkly-staining and these, by a process of fusion, form much bigger mitochondrial granules which are so conspicuous in the middle-piece of the ripe sperm. During the late stages of spermateleosis the manchette forms the lateral boundaries of the middle-piece while its anterior and posterior boundaries are formed by the proximal and distal centrosomes respectively. These observations are strongly supported by the works of Lenhossek (1898), Mollé (1910) and Gresson and Zlotnik (1945 and 1948). Some other previous workers like Leplat (1910), Duesberg (1911), Branca (1924) and Gatenby and Beams (1935), are, however, of the opinion that the manchette appears and disappears in the late spermatids without any apparent function.

Summary

1. In this paper the spermatogenesis of the guinea-pig has been worked out with special reference to the form of the Golgi elements, the formation of the acrosome and the nature of the so-called post-nuclear body.

2. The mitochondria are in the form of fine lightly-staining granules, scattered throughout the cytoplasm, from the early spermatogonia to the late spermatids. During the final stages of sperm formation, those mitochondrial granules which are included in the 'manchette' become darkly staining. It seems probable that by a process of fusion they form bigger and prominent mitochondrial granules which ultimately arrange themselves around the axial filament to form the middle-piece of the ripe sperm. The rest of the mitochondria are sloughed off along with the residual cytoplasm.

3. The Golgi elements in the early spermatogonia exist in the form of a juxta-nuclear mass of darkly-staining granules which are definitely bigger than the mitochondria. In the fully grown spermatogonia, however, these become spread throughout the cytoplasm. In the primary spermatocytes they begin to show a distinct tendency to come together to form bigger granules. Some of these big Golgi granules now collect together to be in the localized condition which is so prominent in the secondary spermatocytes and the spermatids. During the division stages, however, all the Golgi elements, like the mitochondria, become dispersed throughout the cytoplasm. Both the mitochondria and the Golgi elements are thus sorted out, more or less evenly, to the daughter cells.

4. As the process of spermateleosis begins the idiosome becomes closely applied to the nucleus. Most of the Golgi granules in it now begin to coalesce gradually till ultimately a single big Golgi granule is produced. This is situated almost in the centre of the idiosome. Soon after its formation it becomes surrounded by a clear vacuole which gradually increases in size as the idiosome moves towards one side. The single Golgi granule now moves through the vacuole and comes in intimate contact with the nuclear membrane to form the acrosome which is a small structure, to

begin with, but increases in size gradually and also becomes differentiated into two regions—an inner darkly-staining and an outer lightly-staining.

5. As the acrosome grows in size the remains of the idiosome with or without the Golgi elements drift back to the posterior side of the nucleus to be sloughed off with the residual cytoplasm.

6. From the staining reactions and the behaviour, the so-called chromatoid body appears to be merely a part of the unassembled Golgi elements. Similarly the accessory bodies also seem to us to be those Golgi elements which are not consumed in the formation of the acrosome.

7. Neither in Da Fano's (chilled) nor in any other preparation, were the post-nuclear granules observed in any stage of spermatogenesis. In some of our Da Fano's smears, however, deposit of silver was noticed on the posterior part of the nucleus of the ripe sperm. In position, this posterior part of the nucleus is identical with the post-nuclear body of Gatenby and Wigoder (1929). This is, in reality, the dense posterior region of the nucleus itself and not a separate body. It has also been confirmed by employing Feulgen's reaction on smears and sections and the results obtained are in harmony with those of Friend (1936) on the sperms of the British Muridae.

8. A single protoplasmic bead, containing also a few Golgi elements, is present on the middle-piece of the ripe sperm. This is, however, lost while the sperm is within the epididymis.

9. The proximal and the distal centrosomes do not divide. The proximal remains granular but the distal becomes ring-like and travelling down the axial filament marks the posterior boundary of the middle-piece of the ripe sperm.

10. The manchette is a purely cytoplasmic structure in origin. Since it marks the lateral boundaries of the middle-piece it does not seem to disappear without any apparent function, as is urged by some of the previous workers.

Explanation of Plates

All figures except Fig. 50 have been selected from the sectioned testicular material of the guinea-pig, fixed in Flemming-without-acetic and stained with 0·5% iron-hæmatoxylin and have been drawn with a camera lucida at the stage level, using Leitz 6× eye-piece and an oil immersion objective. They were subsequently enlarged four times, thus giving a total magnification of approximately 2,400 times.

Figure 50 has been selected from a smear preparation, made for Feulgen's reaction after fixation in strong Flemming diluted with an equal quantity of water. It was also drawn with a camera lucida, at the table level, using Beck 10× eye-piece and an oil immersion objective, giving a magnification of about 1,700 times.

STUDIES ON INSECT SPERMATOGENESIS

I. Hemiptera-Heteroptera

The Sex Chromosomes and Cytoplasmic Inclusions in the Male Germ Cells of *Laccotrephes maculatus* Fabr. and *Sphaerodema rusticum* Fabr.

By Sukhdev Raj Bawa, *University Research Scholar, Department of Zoology, Hoshiarpur, Panjab (I.)*

I. Introduction

To the best of my knowledge Gatenby (1917) was the first worker to study the cytoplasmic inclusions in the male germ cells of Lepidoptera by modern cytological technique, as almost all the previous workers confined their attention mainly to the chromosomes and mitotic figure.

Subsequently there appeared a series of publications by Bowen (1920, 1922, 1924) on Hemiptera, Lepidoptera, Orthoptera, Coleoptera and Aptera. In his studies Bowen conceives the Golgi body in the form of a chromophilic crescent to which is attached a chromophobic sphere. According to him, the acrosome is a secretory product of the Golgi material. The accounts of Payne (1927), Doyle (1933), Pollister (1930), Mickey (1935), Gresson (1936) and of few others are in accord with Bowen.

On the other hand, it has been suggested by Hirsch (1939) and Nath (1944) that the Golgi bodies are essentially granular or vesicular in form. They grow in size and very often reveal a duplex structure, having an outer deeply-staining chromophilic cortex and an inner lightly-staining chromophobic core. Nath's earlier observations have been confirmed by Baker (1949), (who made use of the Phase Contrast Microscope), Nath, Bawa, Bhardwaj and Gupta (1951), and Nath and Bhatia (1953). Moreover, the acrosome arising directly by the transformation of the Golgi bodies has been described by Nath (1942), Doncaster and Cannon (1920), Cannon (1922), Richter (1940), Nath and Bhatia (1953), Nath and Rishi (1953), and Sharma and Malik (1953).

In view of the conflicting interpretations of different authors on the structure of the Golgi bodies and the mode of acrosome formation, I undertook the present study to survey the process of sperm formation in various orders of insects with particular reference to the Golgi bodies and acrosome formation. The need for such investigations was considered all the more urgent as very little has been reported on Insect spermatogenesis since Bowen's last paper of 1924. Moreover, we possess hardly any knowledge of some insect groups, so far as the fate of the Golgi material and mitochondria in spermatogenesis is concerned. The investigations recorded in this paper—the first of the proposed series of studies on Insect

spermatogenesis—were undertaken in the male germ cells of *Laccotrephes maculatus* and *Sphaerodema rusticum*.

My findings furnish a rather striking confirmation of many of the observations of Bowen (1922) on Pentatomids with respect to the acrosome and mitochondrial nebenkern.

The nuclear changes, especially the behaviour of the sex-chromosomes, are also very carefully studied in both the species. Some of the observations made on fixed preparations of *L. maculatus* have been confirmed under the Phase Contrast Microscope.

II. Acknowledgments

The present work was carried out in the department of Zoology, Panjab University, Hoshiarpur. My thanks are due to Professor Vishwa Nath for granting me necessary research facilities, for the interest he has taken in the progress of my work and for correcting the manuscript of this paper. My thanks are also due to Dr. Ganpati Parshad Sharma for many useful suggestions and his constant advice. I am also indebted to the Entomological section of the Pusa Research Institute, New Delhi, for the identification of the insects.

III. Material and Methods

Observations were made on the germ cells of adults of *Laccotrephes maculatus* (water-scorpion) and *Sphaerodema rusticum* (water-bug). The water scorpions are rather sluggish in their movements, feeding on small insects and aquatic animals found creeping at the bottom of the ponds during spring and summer. The water bug, *Sphaerodema rusticum*, however, is very active in its movements. Both the species were collected in large numbers from 'Budha Nala' (a small stream) near Ludhiana, Panjab (I.).

The testes were dissected from insects in normal saline and were then transferred to Flemming-without-acetic acid, which gave very good results. Bouin's fluid, which was used as control, gave excellent results for the study of chromosomes. After the usual process of dehydration of the testicular material, sections were cut 5–7 μ thick. They were stained with 0·5% iron haematoxylin and mounted in canada balsam. For the study of mature sperm, smears of the vasa deferentia of the testes were made in Flemming-without-acetic acid diluted with an equal quantity of distilled water and stained in 0·5% iron haematoxylin.

IV. Observations

Since the process of sperm formation is more or less similar in the two species of Hemiptera-Heteroptera described here, it has been considered best to give a comparative account of both the species to avoid unnecessary repetition.

(i) *Spermatogonia*

In the resting spermatogonia of *Laccotrephes maculatus* there can be distinguished a juxta-nuclear mass of greyish mitochondrial granules. A few darkly-staining Golgi elements, which are slightly bigger than the mitochondria, can also be easily made out in this mass (Pl. I, Fig. 1). But in *Sphaerodema rusticum* no Golgi elements can be detected in the mitochondrial mass (Pl. III, Fig. 1).

The spermatogonial nucleus reveals a prominent rounded nucleolus and fine faintly-staining chromatin granules in *L. maculatus*, while the nucleolus is very often irregular in outline in *S. rusticum* (Pl. I, Fig. 1; and Pl. III, Fig. 1). Dividing spermatogonia were not observed in *L. maculatus*. On the other hand, a large number of counts of the chromosomes in the spermatogonial metaphase plates were made in *S. rusticum* in which the polar views consistently reveal 28 well-defined chromosomes (Pl. III, Fig. 2). These chromosomes are of various sizes, but the variation is not great, and only two small chromosomes could be differentiated from the rest. The sex-chromosomes cannot be distinguished as such at this stage. During spermatogonial mitosis a spindle makes its appearance with a crescentic centriole at each pole (Pl. III, Fig. 3) and the mitochondrial granules form a sort of palisade round the spindle. These granules seem to be sorted out into two roughly equal parts to the two daughter cells (Pl. III, Fig. 4).

(ii) *Spermatocytes*

In the primary spermatocytes of *Laccotrephes maculatus* and *Sphaerodema rusticum* the mitochondria are small and vesicular in form, while the Golgi bodies, which appear for the first time at this stage in *S. rusticum*, are like crescents, distributed amongst the mitochondria (Pl. I, Fig. 2; and Pl. III, Fig. 5). The Golgi crescents are most probably the optical sections of the Golgi spheres, as distinct Golgi *spheres* and vesicular mitochondria have been observed in the living spermatocytes of *L. maculatus* under the Phase Contrast Microscope. At no stage Golgi *crescents* observed in sectioned material were seen in the living cells of *L. maculatus* (Pl. V, Fig. 1).

As the spermatocytes grow, the Golgi elements as well as the mitochondrial granules increase in size (Pl. I, Fig. 3; and Pl. III, Figs. 6 and 7). Very often both these cell-components reveal a duplex structure with a chromophilic, darkly staining cortex, enclosing a lightly staining chromophobic substance. However, the Golgi elements are bigger in size than the mitochondria and are generally embedded in the mitochondria which form a compact juxta-nuclear frothy mass (Pl. I, Figs. 4, 5 and 7; and Pl. III, Figs. 9–12). The mitochondria seem to reach their maximum size prior to the appearance of the meiotic spindle (Pl. I, Figs. 8 and 9; and Pl. III, Fig. 13). As the nuclear wall breaks down, the mitochondria get scattered in the cytoplasm and are distributed almost evenly to the two secondary spermatocytes (Pl. I, Figs. 10–13; and Pl. III, Figs. 15–18; and Pl. IV, Fig. 19). The Golgi elements also are distributed more or less evenly to the daughter cells during first meiotic division in *L. maculatus*, but I could not trace the Golgi elements at this stage in *S. rusticum*.

A resting stage between the two meiotic divisions does not occur. So far as the mitochondria and the Golgi elements are concerned, the second meiotic division is a repetition of the changes observed during the first division (Pl. I, Figs. 15, 16 and 18–21; and Pl. IV, Figs. 20–22).

In Pl. I, Fig. 2 and Pl. III, Fig. 7 are shown primary spermatocytes in leptotene stage. The fine chromatin threads are so numerous and are arranged in such a way that it is impossible to count the autosome threads. However, the sex-chromosomes have already condensed and stain deeply The process of gradual condensation of the sex-chromosomes can be clearly seen in preleptotene stages in *S. rusticum* (Pl. III, Figs. 5 and 6). The sex-chromosomes can be seen often lying in close contact with the nuclear wall. After the usual process of pairing of the chromatin threads, the chromosomes condense into diplotene threads (Pl. I, Figs. 3–5; and Pl. III, Figs. 8 and 9). The nucleus then enters into a diffuse stage in *S. rusticum*, while no such stage occurs in *L. maculatus* (Pl. III, Fig. 10). During the process of diakinesis, chromosomes further contract, and with the appearance of a split in each chromosome, which will function during the second meiotic division only, dumb-bell shaped tetrads now place themselves at the equator of the spindle (Pl. I, Figs. 6–8; and Pl. III, Figs. 11–14). At each pole of the spindle, which appears fibrillar in the fixed preparations of *L. maculatus*, there is a deeply-staining conspicuous crescentic centrosome (Pl. I, Fig. 10; and Pl. III, Figs. 16 and 17). The crescent-shaped centrioles can be very clearly made out in fresh cells of *L. maculatus* examined under the Phase Contrast Microscope (Pl. V, Fig. 3). In this figure it may be noted that the spindle is not fibrillar; it simply appears as a hyaline fusiform area.

The chromosomal plates at metaphase I in polar view show twenty-two and fifteen distinct pairs of homologus chromosomes in *L. maculatus* and *S. rusticum* respectively (Pl. I, Fig. 9; and Pl. III, Fig. 15). These 22 pairs of chromosomes of *L. maculatus* have been clearly seen and counted in the fresh cells examined under the Phase Contrast (Pl. V, Fig. 2).

The sex-chromosomes during metaphase I cannot be distinguished from the autosomes. During late anaphase I in *S. rusticum* *X* and *Y* chromosomes seem to be connected temporarily by means of granular spindle (Pl. III, Fig. 17). In the late telophase I the spindle usually gives rise to a mid-body at the junction of the two daughter cells (Pl. I, Fig. 12; and Pl. IV, Fig. 19).

Actual formation of the mid-body by the deposition of small granules at the equator of the telophase I spindle has been studied in fresh material of *L. maculatus* under the Phase Contrast (Pl. V, Fig. 4).

Meiosis II immediately follows telophase I without the intervention of any resting stage. In Pl. I, Figs. 14 and 15, and Pl. IV, Fig. 20 are shown metaphase II plates of *Laccotrephes maculatus* and *Sphaerodema rusticum* with the reduced number (haploid) of twenty-two and fourteen chromosomes respectively. In the side views of second meiotic spindles can be seen *X* and *Y* chromosomes lying apposed to each other in *S. rusticum*, while 2 *X* chromosomes and a *Y* chromosome form a pseudo-trivalent almost in the central zone of the spindle in *L. maculatus* (Pl. I, Fig. 17; and Pl. IV, Fig. 21). It will be noted that the reductional division for the

sex-chromosomes is the second meiotic division, during which the autosomes divide equationally.

(iii) *Spermateleosis*

In both the species, *Laccotrephes maculatus* and *Sphaerodema rusticum*, vesicular mitochondria derived from the second spermatocyte, aggregate to form a mitochondrial nebenkern in the spermatid. As revealed by studies of fresh material under the Phase Contrast the earliest spermatid of *L. maculatus* possesses a vesicular nucleus having a hyaline appearance and showing no structure whatsoever within its interior, a mass of closely aggregated mitochondria and a vesicular acroblast (Pl. V, Figs. 5 and 6).

The earliest stages in the process of condensation of the mitochondrial nebenkern have not been traced as the material in both the species does not seem to be favourable for such a critical study. It may be that the earliest condensation stages are so short-lived that they have escaped notice. Similar difficulty was experienced by Bowen (1922) in Pentatomids. The mitochondrial nebenkern, when fully condensed, shows a chromophobic envelope through which pass a few strands from the central chromophilic core (Pl. II, Figs. 22–24; and Pl. IV, Figs. 25–27). Within the chromophilic core can be seen many vacuoles, which can be demonstrated only if the nebenkern is suitably destained. The transverse strands in the chromophobic area of the nebenkern subsequently disappear. The mitochondrial nebenkern now reveals a clear space surrounding the chromophilic core (Pl. II, Figs. 25–27; and Pl. IV, Fig. 28). As the process of nebenkern differentiation proceeds further, the chromophobic substance increases, while there is corresponding decrease of the chromophilic core. During this process of gradual obliteration of the chromophilic core, a number of greyish granules appear in the chromophobic area of the nebenkern. These granules later get dispersed throughout the chromophobic area, while no trace of the chromophilic core is left whatsoever (Pl. II, Figs. 28–33; and Pl. IV, Figs. 29–32). These granules seem to form the sheath of the tail of the mature sperm and correspond to the 'central substance' of Bowen (1922) and 'Sheath substance' of Nath (1925). The axial filament springs up from the centriole and divides the mitochondrial nebenkern into almost two equal halves. The nebenkern elongates and gets constricted into a number of vesicles, which finally seem to be sloughed off (Pl. II, Figs. 34–37; and Pl. IV, Figs. 33 and 36).

The series of changes involved in the gradual disappearance of the chromophilic core and the appearance of the 'central substance' granules in the chromophobic area of the nebenkern have been studied under Phase Contrast in the fresh material of *L. maculatus* (Pl. V, Figs. 7–14).

When the spermatid is formed, the Golgi elements reappear as crescent-shaped bodies and tend to aggregate between the nucleus and the nebenkern. The Golgi bodies finally fuse to form a single acroblast which soon becomes vesicular in nature (Pl. II, Figs. 22 and 23; and Pl. IV, Figs. 23–25). The acroblast further gets differentiated and comes to have a brightly-staining acrosomal granule at its periphery. This granule from

the very beginning of its formation remains in contact with the nuclear wall (Pl. II, Figs. 24–27; and Pl. IV, Figs. 26 and 27). During the process of elongation of the spermatid, the acroblast accompanied with the acrosomal granule travels round the spermatid nucleus for a fairly long time. The acrosomal granule which according to Bowen's terminology is the acrosome, grows in size at the expense of the acroblast. When the acrosomal granule has considerably increased in size it gets disassociated from the acroblast. The acrosome, later on, travels forward in front of the nucleus, while the acroblast seems to be moving back into the tail region and finally disappears (Pl. II, Figs. 28–37; and Pl. IV, Figs. 28–37).

Various changes involved in the formation of the acrosome from the acroblast have been studied very carefully under Phase Contrast in the fresh material of *L. maculatus*. The movement of the acroblast accompanied with the acrosomal granule round the spermatid nucleus in living material of *L. maculatus* was most fascinating to watch (Pl. V, Figs. 6–14).

In Pl. II, Figs. 38–41, and Pl. IV, Figs. 39–41, are shown progressive changes in the position of the acrosome. In the beginning, the acrosome is a button-like structure closely attached to the nuclear wall; later it gets transformed into a triangular area in front of the nucleus, and finally in the mature sperm, the acrosome is seen as a fine thread right at the tip of the sperm nucleus (Pl. II, Fig. 42; Pl. IV, Fig. 42).

The nuclear changes involved throughout the process of spermateleosis need some mention also. In *Laccotrephes maculatus*, to start with, the chromatin is spread out along the periphery of the nucleus enclosing a central area (Pl. II, Figs. 22 and 23). Very soon this demarcation of the nucleus into two areas is lost and the spermatid nucleus now stains very feebly, showing no structure whatsoever within its interior (Pl. II, Figs. 24–29; and 34–37). In a very few cases in *L. maculatus* some faintly-staining granules can be seen along the periphery of the spermatid nucleus (Pl. II, Figs. 31–33).

In *Sphaerodema rusticum* the spermatid nucleus does not reveal any differentiation into chromophilic and chromophobic areas in any stage during spermateleosis. In few of the early stages, however, sometimes there is seen a brightly-staining granule in the interior of the spermatid nucleus. This may be one of the sex chromosomes, which finally loses its identity in later stages of spermateleosis. An important point in the maturing nucleus of the spermatid of both the species of Hemiptera under consideration may be noted that the almost universal process of reversal of the chromophilic cortex and the chromophobic medulla, which accompanies the condensation of the vesicular spermatid nucleus into a compact homogeneously staining sperm head, is conspicuous by its absence.

In addition to the cell components mentioned above a brightly-staining granule is very frequently observed in the spermatids of *Sphaerodema rusticum* (Pl. IV, Figs. 25–27, 32, 33, 36–38). As the spermatid elongates, this granule grows in size and is finally seen moving backwards into the tail region. This granule corresponds to the 'chromatoid body' of Bowen (1924). It is probably one of the Golgi bodies, which does not take part in the formation of acroblast, and gets sloughed off.

V. Discussion

My work on *Laccotrephes maculatus* and *Sphaerodema rusticum* furnishes a striking confirmation of many of the observations of Bowen (1922) on the Pentatomids, regarding the nature and the behaviour of the Golgi elements in the process of spermatogenesis.

According to Bowen, each Golgi body is a rod composed of two substances—a deeply-staining outer rim (chromophilic) nearly surrounding, a more lightly-staining 'Idiosome' (chromophobic).

Nath (1944), on the other hand, is of the view that the Golgi bodies in the form of rods described by Bowen are really the optical sections of *discrete Golgi spheres*.

Nath's views about the granular or vesicular nature of the Golgi body have been fully confirmed by Baker's studies under the Phase Contrast (1949).

It is important to note that at no stage in the process of spermatogenesis, have I observed any crescents or rods in the living testicular material of *Laccotrephes maculatus*, studied thoroughly under the Phase Contrast. The Golgi bodies thus appear as beautiful spheres, each of which shows in sections an outer brightly coloured chromophilic cortex and an inner chromophobic medulla.

It is now universally held that the acrosome owes its origin to the Golgi bodies (Gatenby, 1917, Bowen, 1920, 1922, and 1924, and Nath, 1942, 1944, 1951, 1953). According to Bowen, the Golgi bodies in the hemipteran spermatid fuse to form a single acroblast, which is sloughed off after it has secreted the acrosome. My observations on *L. maculatus* and *S. rusticum* are fully in accord with Bowen's on Pentatomids in this respect.

Payne (1927) in *Gelastocoris* describes the acrosome arising from the fusion of a large number of 'pro-idiosomal spheres' met with in the late growth period of the spermatocytes. These spheres fuse to form an idiosome. The author shows the Golgi bodies clustering round the 'idiosome', but he is unable to say whether they contribute anything to idiosome formation or not. He is also doubtful regarding the origin of the 'spheres'.

Chickering (1927) in Belostomatidae agrees fully with the observations of Bowen (1922), but his account is incomplete as there is no reference to acrosome formation at all.

Pollister (1930) in *Gerris* also agrees with Bowen as regards acrosome formation, but shows the acrosome to consist of a sheath and a core each of which shows further differentiation. I am unable to agree with Pollister regarding these details of the structure of the acrosome.

The mitochondria are present as a juxta-nuclear, granular mass in the spermatogonia of *Laccotrephes maculatus* and *Sphaerodema rusticum*. During growth of the spermatocytes, these granules increase in size, become vesicular and reveal a chromophilic covering, enclosing a chromophobic substance in its interior. The vesicular mitochondria seem to be sorted out into two sub-equal halves in the two meiotic divisions. During spermateleosis, these vesicles coalesce to form a compact nebenkern, which

later on gets differentiated into an outer chromophobic and an inner chromophilic core. Gradually the chromophilic core disappears and a 'central substance' of (Bowen) appears in the form of numerous granules in the chromophobic area. These 'central substance' granules seem to form the sheath of the mature sperm. A number of tail vesicles are also observed along the entire length of the maturing spermatid. Bowen (1920, 1922) was the first worker to study the mitochondria in spermatogenesis with modern cytological technique. My observations are in full accord with those of Bowen.

VI. Summary

1. In this paper, the behaviour of the cytoplasmic elements and the sex-chromosomes in the male germ cells during the course of spermatogenesis has been worked out in two species of Hemiptera-Heteroptera, viz., the water scorpion *Laccotrephes maculatus* Fabr. and the water bug *Sphaerodema rusticum* Fabr.

2. There is multiple sex-chromosome mechanism consisting of $2X$ and a Y chromosome in *L. maculatus*; while there is a single X and a Y chromosome in *S. rusticum*.

3. In both the species, the sex-chromosomes divide equationally in meiosis I, and reductionally in meiosis II.

4. The mitochondria are granular in the spermatogonia and become vesicular during the growth of the spermatocytes. They coalesce to form a nebenkern in the spermatid in both the species.

5. The Golgi bodies are complete spheres revealing a duplex structure in both the species.

6. The Golgi bodies and the mitochondria seem to be equally divided in the two meiotic divisions.

7. There is a single acroblast in the spermatid formed by the fusion of the Golgi bodies. The acrosome gets differentiated from the acroblast; the latter finally disappears in the tail region of the spermatid.

8. The transformation of the spermatid nucleus into the mature sperm nucleus is unusually simple—there being no reversal of the chromophilic and chromophobic substances of the nucleus during the process of spermateleosis.

9. The centrioles in *L. maculatus* and *S. rusticum*, are crescentic.

A.—Acroblast; *A'* or A_1.—Acrosome; *A.Ch.*—Sex-chromosomes; *A.g.*—Acrosomal granule; *A.f.*—Axial filament; *C.*—Centrosome; *C.B.*—Chromophobic area; *Ch.*—Chromosomes; *C.L.*—Chromophilic area; *C.s.*—Central substance; *G.*—Golgi elements; *M.*—Mitochondria; *M.n.*—Mitochondrial nebenkern; *M.B.*—Mid-body; *N.*—Nucleus; N_1.—Nucleolus; *S.f.*—Spindle fibres; *V.*—Tail vesicle.

IX. Explanation of Figures in the Plates

All figures of the Plates I–IV have been drawn with a camera lucida at the table level with spencer 10× eyepiece and oil immersion objective giving approximate magnification of 1,700 times. All the figures of the Plates I–IV except Figs. 6, 14 and 17, Pl. I, and Figs. 2, 8 and 14, Pl. III have been selected from sectioned material fixed in Flemming-without-acetic acid followed by 0·5% iron haematoxylin.

Fig. 42, Pl. II, and Fig. 42, Pl. IV are from smear preparations made by Flemming-without-acetic acid diluted equally with water and stained in 0·5% iron haematoxylin.

All figures of Plate V are from the fresh material of *Laccotrephes maculatus* studied under the Phase Contrast Microscope.

Plate I (*Laccotrephes maculatus*)

Fig. 1. Resting spermatogonia.
„ 2. Primary spermatocyte showing leptotene nucleus, mitochondria and Golgi elements.
„ 3. Primary spermatocyte showing the sex-chromosomes condensed into a deeply-staining body.

FISH SPERMATOGENESIS WITH PARTICULAR REFERENCE TO THE FATE OF THE CYTOPLASMIC INCLUSIONS

I. Spermatogenesis of Elasmobranchs (Hypotremata)

By Hem Sagar Vasisht, *Junior Research Scholar, Government of India, Department of Zoology, Panjab University, Hoshiarpur*

Introduction

In recent years the cytoplasmic inclusions in the germ cells of a large number of animals have been the subject of investigation, but, strange as it would appear, fish spermatogenesis has received very little attention.

To the best of my knowledge Hermann (1882) was the first worker, who gave an exhaustive account of the sperm formation in Selachians. A year later Jensen (1883), and Swaen and Masquelin (1883) published two independent papers on the same subject. Ballowitz (1890) published a paper on tail-formation in fish sperm. Cunningham (1892) worked on the spermatogenesis of a cyclostome, *Myxine glutinosa*. Moore (1895) worked mainly on the nuclear changes in different sharks and rays, e.g. *Scyllium canicula, Scyllium catulus, Pristiurus, Torpedo, Raja macrorhynchus* and *Raja maculata*. During the course of his studies Moore describes an 'archoplasmic vesicle' in the cytoplasm, which as will appear later, should be interpreted as the acroblast or pro-acrosome. Likewise the phenomenon of 'cytoplasmic condensation' must be interpreted as mitochondrial aggregation. Suzuki (1899) published a note on the middle-piece and axial filament of fish sperm. Retzius (1909) also worked on the sperm development of fish.

Since all these workers unfortunately used fixatives containing strong fat-solvents, they could not have been expected to give an account of the Golgi bodies and the mitochondria even if these cell components had been discovered or known sufficiently at that time.

Jean Vaupel (1929) demonstrated the mitochondria and the Golgi bodies in a teleost, *Lebistes reticulatus*, for the first time, by making use of a fixative without a fat-solvent. She has shown a complete degeneration of the Golgi bodies in spermateleosis with the result that the acrosome is conspicuous by its absence. Ratnavathy (1941) worked out the spermatogenesis of the shark, *Chiloscyllium griseum*.

In these series of papers it is intended to publish an exhaustive account of the spermatogenesis of cartilaginous as well as bony fishes, with particular reference to the Golgi bodies and the mitochondria. Unfortunately, this material is very unfavourable for the study of chromosomes, which have a marked tendency to agglutinate.

Material and Technique

The spermatogenesis of nine Elasmobranch species has been worked out in this paper. The names of these species appear below. They all belong to the order Rajiformes, except *Torpedo marmorata*, which belongs to the order Torpediniformes. (1) *Aetomyleus maculatus*, (2) *Aetomyleus nichofii*, (3) *Aetobatus narinari*, (4) *Rhynobatus obtusus*, (5) *Rhynobatus granulatus*, (6) *Dasyatis zugei*, (7) *Dasyatis kuhlii*, (8) *Dasyatis sephen*, and (9) *Torpedo marmorata*.

I started these investigations in 1951. In 1952 I visited different fishing grounds in the suburbs of Bombay during the early hours of the day. The fishing was done with the help of barrier nets. Generally I used to dissect the fish on the spot, but sometimes it was felt necessary to take the catch to the laboratory.

The male genital organs of all the rays and skates studied, except *Torpedo marmorata*, are built up on the same plan as described in *Scoliodon* by Thillayampalam (1928). The testes are a pair of white elongated structures with a pair of vasa deferentia opening to the outer world through the grooves in the claspers. These claspers are only present in the male Elasmobranchs. The testes are situated below the kidneys, extending from the base of the liver to the rectal gland and are attached to the body wall by a fold of peritoneum. In *Torpedo marmorata* the testes are small bean-shaped structures situated at the anterior end of the kidneys. Immediately after the testes were taken out they were put in normal saline, cut into small pieces of not more than one millimeter in diameter, and were transferred to capsules containing different fixatives.

Smears were also prepared for the study of sperms. For smears Flemming-without-acetic acid was diluted with an equal quantity of distilled water.

The testicular material was mainly fixed in Flemming-without-acetic acid, Champy, Altmann, Kolatchew and Bouin. Amongst all the fixatives tried, Flemming-without-acetic acid proved to be the best. This was followed by 0·5% iron haematoxylin. Best results were obtained after fixation in F.W.A. for 24 or 48 hours. The material was washed in running water for the same period as it was kept in the fixative. Sections were cut 5 μ thick.

Acknowledgements

My thanks are due to the staff and the curator, Taraporewala Aquarium, Bombay, and in particular to Dr. S. B. Setna, Director of Bombay Fisheries, for the help, which they all rendered ungrudgingly. I am also grateful to Dr. Vishwa Nath for suggesting this problem to me and for correcting the manuscript of this paper. My thanks are also due to Mr. Ashok Nair for the translation of some French publications.

Observations

As the spermatogenesis of the nine Elasmobranch species described here is more or less similar, it has been considered best to give a compara-

tive account, with occasional references to the existing variations especially in the process of spermateleosis.

Spermatogonia

The earliest spermatogonia in all the nine rays and skates studied are small rounded cells with vesicular nuclei. The nucleus contains chromatin granules, delicate chromatin threads and a distinct darkly-stained nucleolus. The nucleus is large and central in position, with an attenuated layer of cytoplasm. The cytoplasm is clear and does not contain any granules in it (Pl. I, Fig. 1; Pl. II, Fig. 31; Pl. III, Fig. 57; Pl. IV, Figs. 83 and 109; and Pl. VII, Fig. 164). As the spermatogonium grows in size a few dust-like granules make their appearance in the cytoplasm. These are the mitochondrial granules (Pl. I, Fig. 2; Pl. II, Fig. 32; Pl. V, Fig. 129; and Pl. VII, Fig. 177). These granular mitochondria are grey in colour. In *Rhynobatus obtusus*, however, the mitochondria are vesicular (Pl. IV, Figs. 84 to 86). It is further observed that one or more granules, which are comparatively larger and which stain more sharply also make their appearance amongst the mitochondria (Pl. I, Fig. 2; Pl. III, Fig. 58; Pl. IV, Figs. 85 and 110; Pl. VI, Fig. 143; and Pl. VII, Figs. 165 and 177). These are the Golgi bodies. In *R. obtusus*, in a comparatively more grown-up cell, the Golgi bodies clearly appear as vesicles and crescents (Pl. IV, Fig. 86).

Primary Spermatocyte

The primary spermatocyte is the largest cell in the testis. It has a vesicular nucleus, generally containing a nucleolus. During the growth period the mitochondria grow in size appreciably into darkly-staining granules (Pl. I, Figs. 3 to 7; Pl. II, Figs. 33 to 35; Pl. III, Figs. 59 to 61; Pl. IV, Figs. 111 to 114; Pl. V, Figs. 130 to 132; Pl. VI, Figs. 144 and 145; and Pl. VII, Figs. 166, 167 and 178), except in *R. obtusus*, where the mitochondria appear as feebly-staining vesicles (Pl. IV, Figs. 87 to 90). In this species it is seen that the mitochondria, which were vesicular even in the spermatogonia, continue to remain so except that they have now grown in size. In *Aetobatus narinari* at a little advanced stage the mitochondria also become vesicular (Pl. III, Figs. 62 and 63).

It is very difficult to spot out the Golgi elements in the majority of the primary spermatocytes as they are mixed up with the darkly-staining mitochondria. This, however, is not the case in all the cells. A few of the spermatocytes have distinct Golgi bodies. The Golgi bodies do not lie in a particular position, but are scattered amongst the mitochondria. The Golgi bodies are generally very few in number as compared with the mitochondria, and are more often than not in the form of crescents. In *Rhynobatus obtusus* where the mitochondria are vesicular from the very beginning, the Golgi elements are very clear and are sometimes seen to occupy a juxta-nuclear position (Pl. IV, Fig. 89).

A few division stages (meiosis I) in *Aetomyleus maculatus*, *Aetomyleus nichofii* and *Dasyatis kuhlii* have been observed and figured by me. The

Golgi bodies and the mitochondria are probably sorted out, more or less evenly, to the two secondary spermatocytes. During the division of the cell, a well-defined spindle can be noticed. Two prominent sharply-stained centrosomes appear, one at each pole of the spindle. During division stages, the chromosomes always appear as a deeply-stained compact mass (Pl. I, Fig. 8; Pl. II, Fig. 36; and Pl. VI, Fig. 146). During anaphase I, the single chromosome mass splits into two, one mass moving towards one pole and the other to the opposite pole (Pl. I, Fig. 9; and Pl. VI, Fig. 147). During telophase I, two daughter nuclei are formed and the centrosomes disappear from the scene (Pl. I, Fig. 10; Pl. II, Fig. 37; and Pl. VI, Fig. 148). Cytoplasmic cleavage then follows (Pl. II, Fig. 38).

Secondary Spermatocyte

The secondary spermatocytes are smaller than the primary spermatocytes, but bigger than the spermatogonia (Pl. I, Figs. 11 and 12; Pl. II, Figs. 39 and 40; Pl. III, Fig. 64; Pl. IV, Figs. 91, 92 and 115; Pl. V, Figs. 116 and 133; Pl. VI, Fig. 149; and Pl. VII, Figs. 168 and 179). There is a definite interkinetic resting stage, when the nucleus of the secondary spermatocyte is re-formed (Pl. I, Fig. 12; Pl. II, Figs. 39 and 40; Pl. III, Fig. 64; Pl. IV, Figs. 91 and 92; Pl. V, Figs. 116 and 133; Pl. VI, Fig. 149; and Pl. VII, Figs. 168 and 179), and in some cases all traces of chromosomes are lost (Pl. II, Fig. 40). The secondary spermatocytes have the usual complement of mitochondria and Golgi bodies.

In *Aetomyleus maculatus, Aetomyleus nichofii* and *Dasyatis kuhlii* metaphase II shows the chromosomes jumbled up in a single mass (Pl. I, Fig. 13; Pl. II, Fig. 41; and Pl. VI, Fig. 150). This single chromatic mass lies at the equator of the spindle, while at each pole there is a prominent centrosome. The mitochondria are either vesicular or granular. The Golgi bodies and the mitochondria are evenly scattered in the cell. In Pl. I, Fig. 14 is shown a cell in anaphase II. In Pl. II, Fig. 42, and Pl. VI, Fig. 151, are shown two early telophase II stages.

Spermateleosis

Since there is no essential difference in the spermateleosis of the nine Elasmobranch species under discussion, it has been thought best to give a comparative account of this process as has been done in the case of spermatogonia and spermatocytes.

The earliest spermatid reveals in almost all cases, a very darkly-staining excentric nucleus, a few Golgi bodies, juxta-nuclear mitochondria and two centrosomes. The mitochondria are either still granular or have become vesicular (Pl. I, Fig. 15; Pl. II, Figs. 43 to 45; Pl. III, Fig. 65; Pl. IV, Figs. 93 and 94; Pl. V, Figs. 121 to 123; Pl. VI, Fig. 152; and Pl. VII, Figs. 169 and 180).

When the transformation of the spermatid begins, either a single Golgi body advances towards the nucleus to form the acrosome as in *Aetomyleus nichofii, Dasyatis zugei, Dasyatis kuhlii* and *Torpedo marmorata*

(Pl. II, Figs. 47 to 51; Pl. V, Figs. 134 to 136; Pl. VI, Figs. 153 and 154; and Pl. VII, Fig. 181), or a few Golgi bodies come close together and ultimately fuse to form the fore-runner of the acrosome (pro-acrosome) as in *Aetomyleus maculatus, Rhynobatus obtusus, Rhynobatus granulatus* and *Dasyatis sephen* (Pl. I, Figs. 17, 21 and 22; Pl. III, Figs. 66 and 67; Pl. V, Figs. 121 and 122; and Pl. VII, Figs. 169 and 170). The pro-acrosome travels forward along the side of the nucleus and ultimately fuses with its anterior aspect. Sooner or later this darkly-staining pro-acrosome is gradually transformed into a semi-transparent pear-shaped acrosome (Pl. I, Figs. 23 to 30; Pl. II, Figs. 52 to 56; Pl. III, Figs. 72 to 82; Pl. IV, Figs. 97 to 108; Pl. V, Figs. 124 to 128 and 137 to 141; Pl. VI, Figs. 155 to 163; and Pl. VII, Figs. 171 to 176 and 182 to 187).

It must be noted carefully that all the Golgi bodies present in the cell do not take part in the formation of the pro-acrosome. A few, which are left unused, remain as the Golgi remnant and are sloughed off along with the residual cytoplasm (Pl. II, Figs. 49 to 55; Pl. III, Fig. 74; Pl. IV, Figs. 97, 99, 101, 102 and 104; Pl. V, Figs. 125, 127, 136, 137 and 140; Pl. VI, Figs. 155, 160, 161 and 162; and Pl. VII, Figs. 171, 172, 174, 181, 182, 183 and 185).

While the Golgi bodies are taking part in the formation of the acrosome the mitochondria are becoming vesicular and are coming close to one another. These compactly arranged mitochondria lie on one side of the nucleus and are traversed by the axial filament. It appears that during the later stages of spermateleosis, the mitochondria lose their staining capacity. Nevertheless, most of them form a compact sheath of the axial filament in the region of the middle-piece, whereas a few are sloughed off along with the residual cytoplasm, which also contains the Golgi remains. Although mitochondria as such cannot be observed in the middle-piece of the ripe sperm, there is no doubt that the sheath of the axial filament in this region is mitochondrial in nature (Pl. III, Figs. 80 and 81; Pl. IV, Figs. 105 and 106; Pl. V, Fig. 140; and Pl. VII, Figs. 185 and 186).

Concomitant with these changes the two centrosomes of the early spermatid move apart, and there appears an intra-cellular filament between them (Pl. I, Fig. 19; Pl. II, Fig. 46; Pl. III, Figs. 68 and 69; and Pl. VII, Fig. 170). The two centrosomes are named according to their position with respect to the nucleus. The anterior one, which is nearer the nucleus, is called the proximal centrosome, and the posterior one the distal. The proximal centrosome soon moves more anteriorly and comes in touch with the nucleus. It is visible only for a short time as it gets covered by the nucleus at a later stage (Pl. I, Figs. 21 to 23; Pl. II, Figs. 47, 51 and 52; Pl. III, Figs. 72 to 77; Pl. IV, Figs. 98 to 108; Pl. V, Figs. 125 to 127 and 135 to 141; Pl. VI, Figs. 156 and 157; and Pl. VII, Figs. 172, 174 to 176 and 182 to 185). The proximal centrosome does not by any means fuse with the nucleus but remains separate as will be clear from the study of many figures (Pl. I, Fig. 24; Pl. II, Figs. 46, 49 and 50; Pl. III, Figs. 78 and 80; Pl. VI, Figs. 159 and 162; and Pl. VII, Figs. 173 and 186). The granular distal centrosome abuts against the cell wall and seems to give rise to the extra-cellular filament, which forms the tail of the sperm. The proximal

and the distal centrosomes are situated at the anterior and posterior ends of the middle-piece respectively.

One finds that once the distal centrosome touches the cell wall, the cell begins to elongate, and simultaneously the intra-cellular axial filament also begins to lengthen out. With the elongation of the cell the nucleus also begins to elongate (Pl. I, Figs. 23 to 27; Pl. II, Fig. 51; Pl. III, Figs. 72 to 74; Pl. IV, Figs. 100 to 104; Pl. VI, Figs. 156 to 159; and Pl. VII, Figs. 173 to 175 and 183). In *Aetobatus narinari*, the elongating nucleus, which is horizontal in position at first, rotates to a vertical position (Pl. III, Figs. 72 to 75). In *Rhynobatus obtusus* the nucleus is at first obliquely placed, and it then assumes a vertical position. Sometimes a spermatid nucleus is curved due to exigencies of space (Pl. IV, Figs. 100 to 104).

As the nucleus and the acrosome are ripening, the residual cytoplasm containing the Golgi bodies and the mitochondria is pushed down the axial filament in the form of blebs (Pl. III, Fig. 80; Pl. IV, Figs. 105 and 106; Pl. VI, Fig. 162; and Pl. VII, Fig. 186).

In *Dasyatis zugei* after the formation of the middle-piece there appears a constriction at a point of location of the distal centrosome. The piece behind the distal centrosome is the residual cytoplasm, which soon gets separated from the area in front and starts moving backward (Pl. V, Figs. 138 to 140).

The fully ripe sperm has a long cylindrical nucleus with a short acrosome in front, a middle-piece between the two centrosomes behind the head and an axial filament forming the tail or flagellum.

Discussion

As has already been pointed out all the previous workers on the fish sperm used fixatives containing fat-solvents, except Jean Vaupel (1929) and Ratnavathy (1941). But apart from this the fish material is rather refractory so far as fixation is concerned. At any rate, it is not a favourable material for cytological studies. Reference to the difficulties of fixation has also been made by Jean Vaupel and Ratnavathy.

Jean Vaupel carried out her investigation on the spermatogenesis of *Lebistes reticulatus*, a bony fish. Since I am publishing a paper on the sperm of bony fish at a subsequent stage, it is not my intention to review her work here.

Before taking up the work of Ratnavathy (1941) for discussion, it will be profitable to discuss briefly the work of earlier workers, who used exclusively fixatives containing fat-solvents and carried out their investigations at a time when the Golgi bodies and the mitochondria had not even been discovered.

Hermann (1882), the earliest worker on the subject of Elasmobranch sperm, nevertheless, gave a faithful account of what he saw in his preparations. Hermann describes a body, 'nodule cephalique', which is, later on, applied to the surface of the 'kernel' (nucleus) of the 'spermatoblast' (spermatid). The 'nodule cephalique' forms, according to him, the 'cephalic point', which undoubtedly is the acrosome in modern terminology.

The greasy granules of Hermann, which are said to unite to form the 'nodule cephalique', are undoubtedly the Golgi bodies, which have been distorted very much.

Jensen (1883), who studied some fresh Elasmobranch material also describes two refringent bodies in fresh spermatids slightly osmicated. These bodies always take a very deep colouring in osmic acid. They fuse together and form one voluminous body, which ultimately takes a position in a depression at the anterior aspect of the nucleus. Here the voluminous body becomes cylindrical. There is no doubt that the refringent bodies are the Golgi elements, as the Golgi elements being lipoidal are definitely known to blacken with osmic acid. Nath (1933) has employed this technique exhaustively and has demonstrated the Golgi elements in fresh oocytes slightly osmicated. Likewise we have no doubt that Jensen's voluminous body is transformed into the acrosome of the ripe sperm.

Swaen and Masquelin (1883), while working on some Elasmobranch sperms, describe a problematic body, which gradually comes near the anterior aspect of the nucleus and ultimately comes in contact with it. Here also it can safely be concluded that the problematic body of these authors corresponds to my pro-acrosome.

Moore (1895) describes an 'archoplasmic vesicle', which becomes first flattened and then elongates out, together with the nuclear chromatin, forming a definite 'cephalic point to the spermatozoon head'. The 'archoplasmic vesicle' of Moore and his 'cephalic point' obviously correspond to my pro-acrosome and acrosome respectively.

Ratnavathy (1941), working on the spermatogenesis of the shark *Chiloscyllium griseum*, gives an account of acrosome formation. It will be profitable to describe this process in her own words—'the Golgi bodies of the spermatid fuse together in such a manner that an almost homogeneous mass of Golgi substance is obtained which may now be designated as the acroblast. This structure always occupies that pole of the spermatid which is destined to become the anterior end of the sperm and is diametrically opposed to that region of the cell where the centrosome has settled down. The acroblast very soon elaborates within its substance a single small vesicle which, however, soon enlarges and becomes prominent. When it reaches its maximum dimensions it is gradually pushed out of the acroblast and deposited close against the nuclear wall, the acroblast still maintaining its connection with the vesicle for a longer or shorter time. Soon it is filled with a dense substance so that the transparent appearance of the vesicle is lost, and when this change of appearance is effected the acroblast which up to now has been observed clinging to the wall of the vesicle like a lump, gradually separates itself and proceeds in a posterior direction to be later expelled from the substance of the spermatid. The vesicle together with the dense substance that it encloses comes to be known as the acrosome. This structure presently assumes a conical appearance and persists through the later stages of the sperm formation as a thin short apical filament, until in the metamorphosed spermatozoon it presents the appearance of a spirally twisted filament'. I have myself completed investigations on the spermatogenesis of this shark and I hope

to send my paper to the press shortly. I agree with Ratnavathy that the acrosome in *Chiloscyllium* sperm is screw-like, and arises from the Golgi bodies. But I have never come across in my material either the 'acroblast' or the 'acrosomal vesicle' of Ratnavathy. The process of the formation of the acrosome from the Golgi bodies in the shark is exactly like the process described in rays and skates in this paper. In the shark *Chiloscyllium* the earliest spermatid has a few Golgi bodies in the form of granules, which soon come together to form a pro-acrosome, the fore-runner of the acrosome. But there is no indication, whatsoever, of either the 'acroblast' or the 'acrosomal vesicle'.

Summary

1. In this paper the spermatogenesis of nine species of Elasmobranch fishes, i.e. *Aetomyleus maculatus*, *Aetomyleus nichofii*, *Aetobatus narinari*, *Rhynobatus obtusus*, *Rhynobatus granulatus*, *Dasyatis zugei*, *Dasyatis kuhlii*, *Dasyatis sephen* and *Torpedo marmorata*, has been described.

2. The Cytoplasmic inclusions have been thoroughly studied in the spermatogonia, spermatocytes and in the process of spermateleosis.

3. The earliest spermatid has an excentrically placed nucleus, a few Golgi elements coming near one another, vesicular mitochondria and two small centrosomes.

4. During spermateleosis, a pro-acrosome is formed directly from one or more Golgi bodies. This fuses with the nucleus and is transformed into an acrosome.

5. There is a prominent middle-piece in the ripe sperm, having a mitochondrial sheath. The two centrosomes, proximal and distal, are situated at the anterior and posterior ends of the middle-piece respectively.

6. The unused Golgi bodies and the mitochondria are sloughed off along with the residual cytoplasm.

7. The ripe sperm has an elongated nucleus with a short acrosome in front, a prominent middle-piece and a long flagellum.

Abbreviations

A—Acrosome; *A'* or A_1—Pro-acrosome; *A.f*—Axial filament; *C*—Centrosome; *C.s*—Centrosomes; C_1—Proximal centrosome; C_2—Distal centrosome; *C.G*—Chromatin granules; *Ch*—Chromosomes; *G*—Golgi body; *M*—Mitochondria; *M.p*—Middle-piece; *N*—Nucleus; N_1—Nucleolus; *R.C*—Residual cytoplasm; *S.f*—Spindle fibres.

Explanation of Figures and Plates

All figures have been drawn with a camera lucida at the table level with Beck 10× eye-piece and oil immersion objective giving a magnification of approximately 1,700 times. All figures (except Pl. I, Figs. 27, 29 and 30; Pl. II, Figs. 55 and 56; Pl. III, Figs. 75 to 82; Pl. IV, Figs. 103, 105 and 108; Pl. V, Figs. 128 and 138 to 141; Pl. VI, Figs. 161 to 163; and Pl. VII, Figs. 176, 183 and 185 to 187 which are drawn from smears) have been drawn from sectioned material fixed in Flemming-without-acetic acid followed by 0·5% iron haematoxylin.

Plate I (*Aetomyleus maculatus*)

Fig. 1. Earliest spermatogonium.
,, 2. Late spermatogonium showing the mitochondria and the Golgi apparatus.
Figs. 3, 4 and 5. Primary spermatocytes.
,, 6 and 7. Primary spermatocytes showing big granules of mitochondria.
Fig. 8. Metaphase I.
,, 9. Anaphase I.
,, 10. Telophase I.
Figs. 11 and 12. Secondary spermatocytes.
Fig. 13. Metaphase II.
,, 14. Early anaphase II.
Figs. 15 and 16. Early spermatids.
Fig. 17. A late spermatid showing the vesicular mitochondria and the Golgi elements in a group.
,, 18. Spermatid showing two centrosomes.
,, 19. Spermatid showing an axial filament.
Figs. 20 and 21. The Golgi bodies are moving in front in a group.
Fig. 22. Pro-acrosome is formed.
Figs. 23 and 24. Pro-acrosome is transformed into an acrosome.
,, 25 to 27. Spermatids showing the nuclei and the cells elongating.
Fig. 28. Sperm from the sections.
,, 29. Early sperm with the residual cytoplasm.
,, 30. Fully formed sperm.

Plate II (*Aetomyleus nichofii*)

Fig. 31. Early spermatogonium.
,, 32. Spermatogonium showing the mitochondria in the cytoplasm.
Figs. 33 to 35. Primary spermatocytes showing mitochondria and Golgi bodies.

FIG. 36. Metaphase I.
„ 37. Telophase I.
„ 38. Late telophase I.
FIGS. 39 and 40. Secondary spermatocytes.
FIG. 41. Metaphase II.
„ 42. Telophase II.
FIGS. 43 and 44. Early spermatids.
FIG. 45. Nucleus of the spermatid taking more stain due to condensation. Note the two centrosomes in addition to the Golgi bodies and mitochondria.
FIGS. 46 and 47. Late spermatids.
„ 48 to 50. The pro-acrosome is formed.
FIG. 51. Spermatid. Note the elongating nucleus.
FIGS. 52 to 55. Pro-acrosome is transformed into an acrosome.
FIG. 56. Mature sperm.

PLATE III (*Aetobatus narinari*)

FIG. 57. Earliest spermatogonium.
„ 58. Late spermatogonium.
FIGS. 59 to 61. Primary spermatocytes.
„ 62 and 63. Late primary spermatocytes showing vesicular mitochondria and Golgi bodies.
FIG. 64. Secondary spermatocyte.
„ 65. Early spermatid.
„ 66. Spermatid showing a distinct tendency of the Golgi elements to come together to form a pro-acrosome.
„ 67. The pro-acrosome is attached to the nucleus.
FIGS. 68 to 70. Spermatids showing a filament between two centrosomes.
FIG. 71. Spermatid showing the intra- as well as extra-cellular filament.
FIGS. 72 and 73. Acrosome is formed. Note the nucleus in the horizontal position.
FIG. 74. The nucleus has rotated to a vertical position.
FIGS. 75 and 76. The nucleus is seen wriggling out of the cytoplasm.
„ 77 and 78. The late spermatids showing the mitochondria on both sides of the axial filament.
„ 79 to 81. Middle-piece of the sperm is formed and the residual cytoplasm is shown going back.
FIG 82. Complete sperm.

PLATE IV (*Rhynobatus obtusus*)

FIG. 83. Early spermatogonium.
„ 84. Spermatogonium showing the appearance of faint vesicular mitochondria.
FIGS. 85 and 86. Late spermatogonia showing the Golgi elements and mitochondria.
„ 87 and 88. Primary spermatocytes.
„ 89 and 90. Primary spermatocytes. Note the Golgi bodies in a group near the nucleus.
„ 91 and 92. Secondary spermatocytes.
FIG. 93. Early spermatid showing a deeply-stained nucleus, the Golgi apparatus and two centrosomes.
„ 94. Spermatid showing pro-acrosome and two centrosomes.
FIGS. 95 and 96. Pro-acrosome has touched the nucleus.
„ 97 to 99. Acrosome is advancing forward and the axial filament is formed.
„ 100 to 104. Spermatids. Nuclei have started elongating.
FIG. 105. Early sperm.
FIGS. 106 and 107. Note the residual cytoplasm going back.
FIG. 108. Fully developed sperm.

PLATE IV (*Rhynobatus granulatus*)

FIG. 109. Early spermatogonium showing a nucleolus in the vesicular nucleus.
,, 110. Spermatogonium showing the mitochondria and the Golgi apparatus.
FIGS. 111 and 112. Primary spermatocytes.
,, 113 and 114. Primary spermatocytes showing the fully grown mitochondria and the Golgi elements.
FIG. 115. Secondary spermatocyte.

PLATE V (*Rhynobatus granulatus*)

FIG. 116. Secondary spermatocyte.
,, 117. Early spermatid.
FIGS. 118 and 119. In the spermatids the nucleus has started showing condensation.
FIG. 120. Spermatid showing a condensed nucleus and a centrosome near the nucleus.
FIGS. 121, 122 and 123. The pro-acrosome is shown on one side of the nucleus.
FIG. 124. Spermatid showing acrosome.
,, 125. Spermatid with an acrosome and an axial filament.
FIGS. 126 and 127. Spermatid with an acrosome and an axial filament, except that the nucleus has rotated along with the acrosome.
FIG. 128. Complete sperm.

PLATE V (*Dasyatis zugei*)

FIG. 129. Spermatogonium.
,, 130. Primary spermatocyte.
FIGS. 131 and 132. Primary spermatocytes showing the grown-up mitochondria.
FIG. 133. Secondary spermatocyte.
,, 134. Spermatid. Note the pro-acrosome.
FIGS. 135 and 136. Pro-acrosome is still not transformed into an acrosome and the axial filament is seen.
FIG. 137. Pro-acrosome is transformed into an acrosome.
FIGS. 138 to 140. The early sperm showing the blebs of residual cytoplasm.
FIG. 141. Fully mature sperm.

PLATE VI (*Dasyatis kuhlii*)

FIG. 142. Spermatogonium.
,, 143. Spermatogonium, showing the mitochondria and the Golgi apparatus.
FIGS. 144 and 145. Primary spermatocytes showing an excentric nucleus with a nucleolus, the mitochondria and the Golgi bodies.
FIG. 146. Metaphase I.
,, 147. Anaphase I.
,, 148. Telophase I.
,, 149. Secondary spermatocyte.
,, 150. Metaphase II.
,, 151. Early Telophase II.
,, 152. Spermatid.
,, 153. Spermatid. Note the centrosome and the pro-acrosome.
,, 154. Pro-acrosome has come in touch with the nucleus.
,, 155. Pro-acrosome is transformed into an acrosome. Note the two centrosomes.
,, 156. Axial filament is formed in the spermatid.
,, 157. The nucleus is elongating.
,, 158. Note the vesicular mitochondria arranged on both sides of the axial filament, and the proximal and the distal centrosome.
,, 159. The nucleus is shown wriggling out of the cytoplasm.
FIGS. 160 and 161. The cytoplasm is shown receding back.
FIG. 162. Spermatid. Note the residual cytoplasm.
,, 163. Sperm.

PLATE VII (*Dasyatis sephen*)

FIG. 164. Early spermatogonium.

,, 165. Spermatogonium with a vesicular nucleus containing nucleolus and chromatin threads. Mitochondria and the Golgi apparatus is also shown.

FIGS. 166 and 167. Primary spermatocytes.

FIG. 168. Secondary spermatocyte.

,, 169. Spermatid showing a deeply-stained nucleus and the Golgi bodies have come close together.

,, 170. Pro-acrosome is formed. Note an intra-cellular filament between the two centrosomes.

,, 171. Pro-acrosome is transformed into an acrosome.

FIGS. 172 to 174. Spermatids showing the cells and the nuclei elongating.

FIG. 175. The cytoplasm is receding back. Note the Golgi body in the residual cytoplasm.

,, 176. Fully formed sperm.

PLATE VII (*Torpedo marmorata*)

FIG. 177. Spermatogonium.

,, 178. Primary spermatocyte.

,, 179. Secondary spermatocyte.

,, 180. Early spermatid showing a darkly-stained excentric nucleus, a few Golgi bodies, vesicular mitochondria and two centrosomes.

,, 181. Note the pro-acrosome.

,, 182. Pro-acrosome is transformed into an acrosome. Note the axial filament and the unutilized Golgi bodies.

FIGS. 183 and 184. The nucleus and the cell has started elongating.

FIG. 185. Early sperm.

,, 186. Early sperm. Note the bleb of residual cytoplasm.

,, 187. Mature sperm. It has an elongated nucleus with a short acrosome in front, a prominent middle-piece and a long flagellum.

OXIDATION WITH CHLORAMINE-B

Volumetric Determination of Metals by Oxine Method

By Balwant Singh, Apar Singh *and* Sukhdev Raj Kapur
Chemistry Department, Panjab University College, Hoshiarpur

Various metals under specified conditions of *p*H yield crystalline precipitates with 8-hydroxyquinoline (oxine). These precipitates have the general formula $M(C_9H_6ON)_n$, where n is the valency of the metal M. On treatment of the oxinate with dilute hydrochloric acid, the oxine is liberated. It reacts with bromine to give 5 : 7-dibromo-8-hydroxy-quinoline (Arthur I. Vogel, 1948; and H. Diehl and G. F. Smith, 1952).

$$C_9H_7ON + 2\ Br_2 = C_9H_5ON\ Br_2 + 2\ HBr$$

The bromine is obtained by the addition of standard chloramine-B and excess of potassium bromide to the acid solution.

$$C_6H_5SO_2N\ ClNa + 2\ KBr + 2\ HCl = C_6H_5SO_2NH_2 + NaCl + 2\ KCl + Br_2$$

Experimental

A known quantity of a metallic salt was dissolved in water, about 5 grams of ammonium acetate and acetic acid were added and the solution warmed to 60° C. An excess of two per cent solution of oxine in alcohol was added in all cases except in solutions of aluminium, magnesium and uranyl salts where two per cent solution of oxine in 2*N* acetic acid was added to precipitate the metallic oxinates.

After the addition of oxine, ammonium hydroxide was added slowly to make the solution faintly alkaline for the complete precipitation of magnesium oxinate.

The mixture was boiled and allowed to cool. The oxinate precipitate was filtered through a sintered glass crucible, washed with hot water and dissolved in warm hydrochloric acid. About one gram of potassium bromide and a known excess of standard chloramine-B solution were added and the solution largely diluted with 2*N* hydrochloric acid. One gram of potassium iodide was then added to the solution and the liberated iodine was titrated against standard sodium thiosulphate, using starch as an indicator.

From the sodium thiosulphate used in these titrations, the amount of bromine required to form 5 : 7-dibromo-8-hydroxy-quinoline and the amount of chloramine-B used to liberate the bromine and hence the quantity of metal present in the metallic compound was calculated. The results are recorded in the following tables.

TABLE I

Potassium Aluminium sulphate $K_2SO_4 . Al_2(SO_4)_3 . 24H_2O$

Substance taken.	0·102*N* chloramine-B added.	0·100*N* $Na_2S_2O_3 . 5H_2O$ used.	0·102*N* chloramine-B used.	Substance found.	Aluminium calculated.

0·12324	45·00	8·30	37·26	0·12318	0·001215

1 c.c. of 0·1073*N* chloramine-B ≡ 0·003306 gm. of $MgSO_4 . 7H_2O$.
≡ 0·0003262 gm. of Magnesium.

From these results it is concluded that aluminium, copper, zinc, cadmium, cobalt, nickel, uranium and magnesium can be determined volumetrically by the oxine method using chloramine-B as an oxidizing agent.

SUMMARY

Aluminium, copper, zinc, cadmium, nickel, cobalt, uranium and magnesium are precipitated as oxinates which dissolve in hydrochloric acid liberating oxine. An excess of potassium bromide and a known volume of

standard chloramine-B are added to the acid solution. The potassium bromide is oxidized by the chloramine-B to bromine which reacts with the oxine to form 5 : 7 dibromo-8-hydroxy-quinoline. The excess of bromine is determined by adding potassium iodide to the solution and titrating the liberated iodine against standard sodium thiosulphate solution. From the thiosulphate used in the titrations, the amount of bromine required to form 5 : 7 dibromo-8-hydroxy-quinoline and the amount of chloramine-B used to liberate the bromine and hence the amount of metal present in the metallic compound is calculated.
